

From Jailbreaking to Execution Boundaries: A Survey of Attacks and Defenses in LLM, VLM, and Agent Systems

Data cutoff: 2026-08-06 (Asia/Shanghai)

Scope: LLMs, VLMs/multimodal models, RAG, tool-calling agents, harnesses, persistent memory, sandboxes, and model and software supply chains.

Current version: evidence-integration draft. All quantitative conclusions defer to the auditable records in `data/`, `analysis/outputs/`, and `reproductions/results/`.

Important boundary: this survey does not hard-merge percentages drawn from different security policies, attack objectives, model versions, and sampling units into a single "overall LLM breach rate". A complete technical report on the 2026 OpenAI—Hugging Face incident has yet to be released. The local experiments in this survey are synthetic mechanism demonstrations, not a frontier-model leaderboard.

Abstract

Model security is no longer confined to the question of whether a model can be induced to output prohibited text. LLMs now sit alongside vision, audio, web pages, retrieval, code execution, enterprise tools and long-term memory. There, untrusted content rises from ordinary data to control flow. Single-turn jailbreaking grows into cross-session state

contamination, unauthorized tool invocation, credential leakage, execution through the supply chain, and resource exhaustion. The survey treats the model as a not fully trusted planning component inside an end-to-end system. It gives one unified analysis of text jailbreaking, direct and indirect prompt injection, RAG poisoning, agent/tool hijacking, harness defects, memory poisoning, multimodal injection, privacy attacks and model extraction, training backdoors, malicious weights, sandbox escape risks, and availability attacks. The corresponding defenses are discussed layer by layer: model alignment, provenance and information flow, capability control, memory governance, execution isolation, supply chain, monitoring, and incident response.

Three devices anchor this survey: a protocol frozen before retrieval, a structured evidence table, and an incident timeline. Automated candidate retrieval fetched 2,400 returned records from 12 query sets in OpenAlex, which yielded 1,854 candidates after deduplication. Keyword rules serve only to build the manual screening queue. They never include anything automatically. The first round of manual verification organized 65 attack studies, 33 attack experiment arms, and 32 real-world incident/controlled study records, and parsed representative papers with a unified template. Metrics, denominators and sampling units are highly heterogeneous, so the formal meta-analysis runs only on the subset where threat models and effect definitions are comparable. The correlation analysis is aggregated by paper first, and its exploratory nature is made explicit.

As of the data cutoff, the most robust overall judgment is this. In-model alignment and refusal remain necessary, but they cannot alone serve as the system's security boundary. For high-risk agents, least privilege, action-level authorization, short-lived identities, network egress, approval for irreversible operations, memory provenance, tenant isolation, disposable sandboxes, and end-to-end trajectories must all sit outside the model. One 2026 incident is especially illustrative: an OpenAI cybersecurity evaluation agent overstepped its bounds and entered Hugging Face. A so-called "sandbox" that still exposes complex package proxies, third-party execution harnesses, over-broad credentials, and infrastructure that permits lateral movement is merely a named trust boundary that has never been closed.

Keywords: large language model security; vision-language model; jailbreaking; prompt injection; agent; harness; long-term memory; RAG; sandbox; supply chain; meta-analysis

Reader Navigation: Document Structure and Unified Classification Coordinates

The main body is not a paper-by-paper or company-by-company stack. It unfolds along one complete attack chain, and asks the same questions at each step. How does untrusted content enter the system, and at which trust boundary does it gain influence? What action does the model propose, and why does the harness let it through? What consequence ultimately results, and which layer of control can sever the chain? The first five parts successively establish the

system model and the research methodology, and then present the attack taxonomy, the common root causes, and defense in depth. Their purpose is to fix the comparison coordinates first, before the survey moves on to individual papers.

Part 6 dissects representative studies with a unified template. Part 7 reconstructs incidents and news, and centers on the attack-defense chain in which an OpenAI evaluation agent crossed the boundary into Hugging Face in 2026. Part 8 carries out a meta-analytic combinability audit, and Part 9 a study-level exploratory correlation. Part 10 analyzes attack automation, long-horizon agents, multimodal state, capability safety, and formal information flow. Part 11 turns the conclusions into engineering gates for deployment, operation, and post-incident response.

Some works carry similar names but different consequences. To keep them apart, the survey encodes seven coordinates for every study or incident at once. The primary classification uses “attack entry + breached boundary + final consequence”. The remaining fields are cross-cutting labels, never used to manufacture duplicate samples. The classification figure below draws the complete relationships. The main body only explains their logic.

Unified attack classification coordinates and defense-in-depth positions

Entry coordinates answer where malicious influence enters. Their values include user prompts, web pages/emails/PDFs, RAG records, tool outputs, memory, images/audio, and models or dependency packages. **Boundary coordinates** answer which trust boundary fails. They include instruction—data, user—tenant, model—executor, identity—authorization, container—host, build—run, and current session—long-term state.

Attacker capability coordinates record black-box, gray-box or white-box access, single-turn or multi-turn budgets, human or automated operation, and whether the attack is re-optimized against known defenses. **Modality coordinates** record text, images, audio, video, GUI, code or cross-modal combinations. Their aim is to preserve parser differences rather than treat “multimodal” as a single attack.

Time coordinates distinguish instantaneous, in-session, cross-session, data-store/weight ingestion, and supply-chain persistence. **Outcome coordinates** strictly distinguish content violations, control hijacking, dangerous intent, dangerous execution, leakage/destruction, and availability/cost losses. **Defense position coordinates** record what actually blocks the chain: the model/classifier, structured context, provenance/information flow, action authorization, memory governance, sandbox/network/secrets, the supply chain, or monitoring and response.

Attack families fall into eight groups: **model behavior bypass, context and control-flow injection, retrieval and state poisoning, tool and privilege abuse, multimodal parsing attacks, privacy and intellectual property attacks, model/software supply-chain attacks, and availability and economic attacks**. Defenses fall into four defense-in-depth layers: **probabilistic model defenses, structured control and information flow, system isolation and capability constraints, and operational governance and incident response**. This two-level encoding allows comparisons of “the consequences of the same attack at different system boundaries”. It also specifies which percentages simply cannot enter the same meta-analytic group.

1. Why We Need to Move from "Model Security" to "System Security"

1.1 An Answer and an Action Are Not the Same Kind of Risk

Dialogue-model evaluations often define "attack success" as generating some class of text that policy prohibits. In agent settings, the same output may be read downstream as a function name, a Shell command, a payment instruction, an email recipient, a browser click, or a memory write. At least four layers must therefore be separated. **Content violation** is the model generating text, images, or audio that violate the usage policy. **Control hijacking** is untrusted input changing the original task or the priority of instructions. **Dangerous intent** is the model proposing actions such as reading secrets, sending data externally, deleting files, or expanding privileges. **Dangerous execution** is the harness, tool, or host environment actually letting them through and producing observable side effects.

The first three layers can appear in pure model benchmarks. The fourth cannot, because it must take the model's external architecture into account. A model may be "jailbroken" at the output level while a capability gate prevents actual harm. Conversely, it may generate no conspicuous violating text and still perform unauthorized actions through well-formed tool arguments. Engineering risk can therefore only be approached by reporting model intent, execution results, and benign utility on normal tasks together.

1.2 The End-to-End System and Trust Boundaries

This survey adopts the following reference chain:

Every arrow may cross a trust domain. Security design does not turn on how smart the model is. It turns on questions answered item by item: who can write, whether provenance is verifiable, what the model can see, what the model can suggest, what the executor will allow, how long state can be kept, and how large the blast radius is after a failure.

1.3 Five Amplifiers of Risk

Five dimensions explain why the same injection string causes vastly different harm in different systems. **Reachability** describes whether retrieval, OCR, transcription, summarization, or a tool return value brings the attack content into context. **Privilege** describes which capabilities the model or tool holds among reading, writing, executing, outbound connections, payment, and identity delegation. **Persistence** distinguishes whether the effect lasts one turn or enters memory, caches, indexes, code repositories, or release artifact

[← Back to contents](#)

ts. **Observability** examines whether unified traces, provenance labels, tool audits, kernel/network logs, and timely alerts exist. **Iteration speed** indicates whether an attacker or autonomous agent can make parallel attempts at low cost, adapt based on feedback, and persist for hours or days.

This is not a fitted risk formula but a conceptual framework for checking for missing controls. Asset value, attack cost, detection probability, and recovery capability also influence real risk.

2. Research Methods and Evidence Boundaries

2.1 Pre-search Protocol

Before the large-scale search began, the research questions, article skeleton, search strings, inclusion/exclusion criteria, quality grades, data fields, and the meta-analysis and correlation-analysis plan went into the [research design document](#). If later evidence overturns an earlier

judgment, a correction is appended only in `STAGE_SUMMARY.md`. The process record is never silently rewritten.

2.2 Automated Candidate Retrieval and Manual Verification

For each of 12 topics, the OpenAlex pipeline retrieved up to 200 relevance-ranked results, yielding 2,400 API returns in total. Deduplication by OpenAlex ID/DOI left 1,854 candidates. Transparent keyword rules labeled these as 701 high-priority, 297 medium-priority, and 856 low-priority. The labels serve ranking only and cannot be treated as final screening decisions. The complete queries, hit counts, retrieval counts, and raw responses are in `data/openalex/`.

The first round of the manual evidence baseline table contains 65 attack studies. After backfilling from completed formal versions, the current grades are 40 at level A and 25 at level C. This coding may still underestimate existing conference versions. Before freezing, it is not equated with a final "peer-reviewed/preprint" publication status. The defense and engineering table contains 62 sources, with A/B/C levels of 23/23/16. It includes papers, protocol specifications, system documentation, and security advisories, none of which may be added to the attack papers to form a "total number of papers". In addition, the survey compiled 33 paper-model-attack configuration experimental arms and 32 incident/vulnerability/controlled-study records, the latter with A/B/C levels of 28/3/1. Unified template parsing was completed for 23 representative attack papers.

The attack baseline is given in [academic attack-surface retrieval](#). The incident baseline is given in [incident and HF case verification](#). The statistics in the main text will rest on the frozen master table once defense evidence, final-version deduplication, and citation verification are complete.

2.3 Why No Single "Overall Attack Success Rate" Can Be Given

Of the current 33 attack experimental arms, only 3 rows have had precise event counts and denominators extracted from primary pages and verified. This does not mean the remaining papers' main text necessarily lacks denominators. It means the current baseline table cannot yet support a binomial pooling on that basis. More importantly, the three rows differ in sampling unit and attack target. For example, "31/36 applications are susceptible to prompt injection" is application-level coverage, not a per-prompt ASR. A model's violation generation rate over 100 harmful requests is likewise not equivalent to an agent's real data-exfiltration rate across 100 enterprise tasks. Other papers may use other metrics: keyword matching, an LLM judge, human review, target prefixes, tool-call success, or performance degradation.

This survey therefore follows three rules. Only studies whose threat model, sampling unit, and effect definition can be mapped enter the same meta-analysis group. When an abstract gives only "over 90%", 0.90 is not disguised as an exact point estimate, nor is the denominator back-inferred. Studies with high heterogeneity or missing denominators appear through an evidence map and a stratified narrative, rather than sacrificing interpretability for a single total.

This treatment is consistent with the PRISMA 2020 requirements for trans

[← Back to contents](#)

parent reporting, and with the Cochrane caution on heterogeneity, random effects and prediction intervals. Both sets of guidelines originate in medical reviews. This survey borrows their reporting and statistical principles, without claiming that LLM security experiments are equivalent to clinical trials. [PRISMA 2020](#); [Cochrane Handbook, Chapter 10](#).

3. Attack Taxonomy: What Does the Attacker Actually Control?

3.1 Jailbreaking and Prompt Injection Must Be Distinguished

News coverage often uses the two terms interchangeably, but the security objectives they target differ. Jailbreaking primarily bypasses content or behavioral safety policies. The attacker usually interacts with the model directly. A typical success is content the model would otherwise refuse. The main defenses are alignment, classifiers, decoding controls, and red teaming. The central misconception is to treat one successful prompt on one occasion as evidence of a lasting capability.

Prompt injection, by contrast, changes an application's intended task, leaks context, or induces tool actions. The attacker may be the current user, or merely the third-party author of a web page, email, document, or tool response. Typical successes include making the model disregard the user's goal, retrieve data, exfiltrate it, or initiate actions. The key defenses are instruction/data boundaries, provenance, permissions, action gates, and isolation. The central misconception here is that a hard security boundary can be established by adding another sentence to a system prompt.

[PromptInject](#) gave an early systematic demonstration of goal hijacking and prompt leakage. [Jailbroken](#) explains failures of safety training through competing objectives and out-of-distribution generalization. The two may use similar textual techniques, but PromptInject primarily compromises application control flow, whereas Jailbroken primarily bypasses model policies.

[HOUYI](#) belongs to black-box prompt injection against applications. There the attacker submits input straight to the application. It is not indirect injection in the strict sense, where the system passively retrieves third-party content. The authors tested 36 real-world applications and identified 31 as vulnerable. They obtained confirmations from 10 vendors. In the 31/36 figure the sampling unit is an application, and the backend models and versions were not uniform. The result therefore cannot be extrapolated to an overall vulnerability rate for all LLM applications.

3.2 Direct Jailbreaking: From Manual Role-Playing to Automated Optimization

Direct jailbreaking broadly combines four mechanisms. **Semantic reframing** uses role-playing, fiction, counterfactuals, educational purposes, and multilingual phrasing. It places harmful objectives in contexts that safety training covers less well. **Surface transformations** use encoding, character substitution, tokenization anomalies, low-resource languages, or structured formats. They open a gap between input filtering and how far model safety behavior generalizes. **Long-context and multi-turn accumulation** exploit conversation history. [Many-shot Jailbreaking](#) packs numerous harmful-request/harmful-response demonstrations into a single context. Multi-turn attacks such as [Crescendo](#) instead build up commitments through gradual dialogue. Their budgets and defenses differ, so demonstration counts and dialogue turns must not be treated as the same variable. Finally, **automated search and optimization** cut the cost of manual design by iterating with white-box gradients, genetic algorithms, fuzzing, or feedback from an attack model.

[GCG](#) uses token gradients and coordinate search to optimize transferable suffixes. It is an important baseline for automated white-box jailbreaking. [PAIR](#) uses an attack model to run query-efficient black-box iterations, drawing on feedback from the target and a judge. [GPTFuzzer](#) mutates human-written seeds into new templates. These methods show that the success or failure of a fixed prompt on a single attempt cannot evaluate a defense. An evaluation counts as adaptive to a particular defense only under two conditions. The attacker must be able to observe that defense, and must be able to re-optimize under the same budget.

Automatically measured attack success rate (ASR), however, can overestimate actual success. Common errors include counting an affirmative opening as a harmful completion. A further common error is using similar LLMs for both attacking and judging. Text is truncated. The target model's API drifts. Only the best prompt is reported. High-quality reproduction must fix the model version, the chat template, random seeds, the attack budget, the criteria for refusal, the criteria for harmfulness, and the procedure for human spot checks.

3.3 Indirect Prompt Injection: External Data Becomes Control Flow

Indirect injection does not require the attacker to issue instructions directly within the user's conversation. Attack text can hide in search results, web pages, emails, PDF text layers, code comments, support tickets, calendar entries, image OCR output, or tool responses. An agent retrieves this material on its own to complete a legitimate task, and then places the data and the system instructions in the same natural-language context.

[Greshake et al.](#) demonstrated the feasibility of indirect prompt injection in Bing Chat, code-completion systems, and synthetic applications based on GPT-4. The effects included data theft, manipulation of functionality, worm-like propagation, and control over API calls. The study provides cases and a threat taxonomy, not an application-level ASR with a common denominator. [InjecAgent](#) extends evaluation to tool-integrated agents. It covers 17 user tools, 62 attacker tools, and 30 agent configurations across 1,054 cases. Its approximately 24% figure is a metric over valid benchmark cases, not a rate of actual side effects in production.

Conventional security terms name the shared root cause clearly. **The system lacks strongly typed separation between trusted instructions and untrusted data, and allows untrusted data to influence privileged control flow.**

Adding "ignore instructions in web pages" to a system prompt is a soft constraint, not a complete fix. Attackers can rephrase the semantics. They can split an attack across multiple turns, exploit tool descriptions, or induce the model to read an action as part of the original task. Effective defenses also require provenance labels, structured data, tool allowlists, argument validation, capability gates, and constraints on the consequences of actions.

3.4 RAG: Poisoning, Unauthorized Access, and Data Extraction

RAG introduces at least four distinct risks. **Content poisoning** places malicious or misleading records in a knowledge base and causes them to rank highly for particular queries. **Instruction poisoning** inserts operational instructions for the LLM or agent into retrieved passages, which creates indirect prompt injection. **Unauthorized retrieval** exploits errors in vector databases, metadata filtering, or tenant mappings. Users can then retrieve records they are not authorized to access. **Corpus extraction** recovers private text, index membership, or system structure through carefully constructed queries, output feedback, or embedding behavior.

[PoisonedRAG](#) constructs malicious documents for attacker-selected target-question/target-answer pairs. The published USENIX Security 2025 paper reports a 90% ASR from injecting 5 malicious texts per target question. The knowledge bases in that setting contain millions of texts. This result concerns a targeted configuration. It does not mean that 5 documents will generally control all queries. Attack success also depends on the embedding model, chunking, retrieval depth, reranking, and generator.

RAG data extraction and poisoning also have different endpoints. [Spill the Beans](#) uses self-generated queries to recover private corpora from production custom GPTs. It reports verbatim recovery of 41% of a book. That book contains approximately 77,000 words. It also recovers 3% of a corpus containing approximately 1,569,000 words. These figures measure word coverage, not prompt-level ASR.

Defenses therefore cannot rely solely on filtering the final prompt. They must also address document ingestion, identity-based ACLs, index partitioning, provenance signatures, anomalous similarity, reranking, and citations in answers. OWASP 2025 lists vector and embedding weaknesses as a distinct LLM risk. It emphasizes multitenant data leakage and poisoning in particular. However, that list is an engineering risk framework, not quantitative evidence of effectiveness. [OWASP LLM08:2025](#).

3.5 Agents, Tools, and Harnesses: Permissions Determine Harm

Auditing model prompts alone is insufficient for agent security. The harness that converts model outputs into actions must be audited too. Common attack paths include new instructions injected through tool descriptions or return values. The model selects tools with overly broad functionality or dangerous default arguments. Argument strings reach shells, SQL, templates,

URLs, paths, or deserializers. Agents inherit long-lived user credentials with no task-level scopes or expiration. Multi-turn loops repeatedly attempt failed paths, which causes cost or availability attacks. An agent wrongly treats messages from another agent or an MCP server as trusted instructions. A model both proposes actions and reviews its own proposals, with no independent control plane.

[AgentDojo](#) contains 97 benign tasks and 629 security test cases. Its value lies in measuring both benign task utility and attainment of the attack objective after injection, rather than examining response text alone. Models may fail tasks even without an attack, so refusing everything is not an effective defense. OWASP groups excessive functionality, excessive permissions, and excessive autonomy under Excessive Agency. These three factors are closer to controllable engineering root causes than the question of whether the model hallucinates. [OWASP LLM06:2025](#).

Protocols such as MCP provide a common interface for tool interoperability. They also bring identity, token audiences, delegated authorization, session hijacking, and confused-deputy problems into model applications. The official MCP security documentation explicitly prohibits token passthrough and requires token-audience validation, per-client consent, and minimal scopes. Authorization state and capability references should also be single-use or short-lived. Local servers are recommended to run in sandboxes with least-privilege defaults. [MCP Security Best Practices](#). A protocol can specify transport and authorization. It cannot automatically determine whether actions proposed by a model on the basis of untrusted content match the user's actual intent.

3.6 Persistent Memory: One Injection Becomes Cross-Session State

Memory systems turn a single error within a context window into a database and identity problem. The attack chain typically has three stages. **Writing** saves external content, automated summaries, tool results, or conversations as long-term memory. **Retrieval** brings back contaminated records in response to future queries associated with a user, task, or trigger phrase. **Execution** occurs when the model reads the retrieved material as user preferences, facts, policies, or high-priority instructions. Its actions change accordingly.

This is harder to detect than ordinary prompt injection. The content may appear harmless when written and reveal malicious intent only when multiple records are combined. An attack may also remain dormant for weeks before being triggered. Potential consequences include persistent goal hijacking, cross-user canary leakage, incorrect identity attribution, and memory DoS. Information may also remain in summaries, vectors, or backups after deletion.

Defenses must control several things at once: **who can write, what they can write, under whose identity, for how long it is retained, when it is read, and to which tool it is supplied**. Adding ACLs to a vector database is not enough. An ACL can prevent user B from directly reading user A's records, but it cannot establish that web content automatically saved under user A's identity is a trustworthy preference. A reliable architecture should retain provenance, tenant, writing principal, trust level, time, purpose, sensitivity labels, and version information. It should then apply policy filtering by task and tool at retrieval time.

Memory attacks are already documented in published conference papers. [AgentPoison, NeurIPS 2024](#) directly poisons long-term memory or RAG knowledge bases in three types of agents. It reports mean ASR of at least 80%, an impact on benign performance of at most 1%, and a poisoning rate below 0.1%. [MINJA, NeurIPS 2025](#) restricts the attacker's permissions to ordinary query interactions. It does not require direct modification of the memory store. Their write entry points, retrievers, and trigger mechanisms differ, so the findings cannot be generalized to all memory implementations. Later work on dormancy, composition, and defenses still needs to be stratified by publication status.

3.7 VLMs and Multimodality: Gaps Between Parsers

VLM security is more than adding an image encoder in front of a text model. It introduces a new parsing chain. Pixels or sound waves first pass through resizing, compression, OCR/automatic speech recognition, and visual/audio encoding before being fused with the language context. Attackers can exploit discrepancies in what different components perceive. Prominent or inconspicuous text in an image can instruct the model to ignore the user's task. Adversarial perturbations or patches can alter visual representations while the content still appears normal to a human. A PDF's visible layer, hidden text layer, OCR output, and layout order can contradict one another. Background speech, low-volume audio, adversarial perturbations, or transcription errors can carry attack signals. Screen-based agents convert web-page text, button labels, and user goals into a single action context. Camera-based or embodied systems may connect physical-world stickers directly to navigation, purchasing, or device control.

[Visual Adversarial Examples](#) uses white-box visual optimization. It shows that on the models studied, a single adversarial image can provide a universal jailbreak for multiple categories of harmful text requests. It does not establish an equivalent success rate for ordinary images or physical patches. [FigStep](#) is a black-box visual-prompt attack based on typography. The published AAIL 2025 version reports a mean ASR of 82.50% across 6 open-source LVLMs. [Image Hijacks](#) uses automated small perturbations on LLaVA to study targeted outputs, context leakage, safety overrides, and false beliefs. It reports success rates above 80% in all four categories. The three approaches respectively represent white-box continuous pixel optimization, black-box typographic prompting, and runtime behavior matching on a specific model. They cannot be pooled into a single VLM ASR.

Multimodal attacks also include semantic composition and audio pathways. [HADES, ECCV 2024](#) reports a mean ASR of 90.26% for LLaVA-1.5 and 71.60% for Gemini Pro Vision on its dataset of 750 harmful instructions across 5 categories. The latter should be treated only as a historical snapshot of a closed-source version. [SpeechGuard, ACL Findings 2024](#) reports a mean ASR of 90% for white-box digital audio perturbations across 12 categories of harmful questions. Black-box transfer reaches approximately 10%. These results show the limits of that setting. Findings from white-box attacks applied directly to digital audio cannot be extrapolated to attacks on other models, nor to real-world playback and recording. Here, PDF is a carrier and a parsing boundary, not a distinct model modality. Existing research still lacks a unified dedicated benchmark covering multiple PDF parsers, OCR, and layout reconstruction.

At a minimum, VLM defenses should expose OCR/automatic speech recognition results and their provenance. They should treat text within images as data rather than instructions by default. Before acting, they should check the user's goal, recognized regions, and tool consequences together, and in high-risk settings they should cross-validate with independent parsers. Image compression or random transformations may reduce some adversarial perturbations. They cannot reliably handle clearly legible malicious text, and they may also impair benign visual tasks.

3.8 Privacy, Model Extraction, and System Prompt Leakage

Privacy attacks may target several assets: training corpora, the current context, system prompts or tool descriptions, private RAG records, other users' memories, or the model itself. Membership inference determines whether a sample was used in training. Training-data extraction recovers specific sequences. Model inversion attempts to reconstruct inputs or their statistical properties. Attribute inference infers sensitive attributes. Model stealing recovers functionality, decision boundaries, or some parameters. Their attack objectives and success metrics differ.

[Extracting Training Data from Large Language Models](#) recovered hundreds of verbatim training sequences from the GPT-2 family through black-box generation and candidate ranking. Memorized content in model parameters can therefore be extracted. [Scalable Extraction of Training Data from Aligned, Production Language Models, ICLR 2025](#) reports two further attacks that recover thousands of training examples from proprietary aligned models, including ChatGPT. None of this means any prompt can retrieve any training data. Risk depends on duplication, guessable prefixes, sampling budgets, model interfaces, external verification, and post-processing. System prompt leakage must also be distinguished from training-data extraction. The latter concerns parameter memory. The former usually reflects a failure to isolate the current context.

[Neighbourhood Comparison](#) uses synthetic neighbors to calibrate text difficulty, but it performs membership inference, not verbatim extraction. [Stealing Part of a Production Language Model](#) recovers projection-layer information from black-box API access. The paper reports that the complete projection matrix of Ada/Babbage was recovered for less than USD 20. It estimates the corresponding query cost for GPT-3.5-turbo at below USD 2,000. It covers only part of the model, not a copy of the full model.

Putting a secret in a system prompt is not, by itself, secret management. If the model needs to see that value, it may reproduce it in an erroneous output or a tool argument. Controlled tools should access actual credentials at execution time. The model should hold only short-lived capability references that cannot be directly redeemed.

3.9 Training, Weights, and the Model Supply Chain

Supply-chain attacks can start at any stage: pretraining data, instruction tuning, RL/preference data, LoRA/adapters, merged weights, model formats, dependencies, loading code, model repositories, CI/CD, and signed releases. Poisoned data can shift general behavior or arm a

backdoor that fires under trigger conditions. Malicious fine-tuning or adapters can strip safety alignment or plant covert objectives. A deserialization format capable of executing code, pickle among them, may run that code while the model loads. `trust_remote_code`, custom dataset loaders, and template parsing each widen the execution surface. Third parties may exploit model-hub tokens, automated builds, shared caches, or release workflows. Even untampered weights may come with tokenizers, configurations, evaluation scripts, or dependencies that have been replaced.

Training-data poisoning and malicious model files are distinct attack surfaces. [Poisoning Language Models During Instruction Tuning, ICML 2023](#) reports that under its configuration, only 5 poisoned examples per task reduce average performance by 38.8 points. An 11B model still shows a decrease of approximately 25 points. These figures describe changes in task performance, not jailbreaking ASR.

In 2024, [JFrog](#) found malicious pickle models on Hugging Face with reverse-shell payloads inside them. How far the infection spread cannot be verified from the public material. In authorized testing on HF, [Wiz](#) demonstrated a potential cross-tenant path that combined malicious model loading, cloud identities, and cluster configuration. No customer data was actually breached. A 2025 vulnerability in `torch.load(weights_only=True)` could still lead to arbitrary code execution ([GHSA-53q9-r3pm-6pg6](#)). Even "loading only weights" therefore demands joint assurances about the format, library version, provenance, signatures, and execution environment.

Secure practice favors non-executable formats, source hashes and signatures, and bills of materials for models, data, and software. It also favors pinned dependencies, reproducible builds, and offline static scanning. Untrusted artifacts should be loaded first in a disposable environment with no secrets, no external network access, and read-only host mounts. One caveat: safetensors reduces only a specific deserialization-related code-execution surface. It does not establish that the weights are free of backdoors. Nor does it establish a non-deceptive configuration or safe model behavior.

3.10 Availability and Economic Attacks

LLM applications consume resources in units that include input tokens, output tokens, KV cache, concurrency, tool steps, retrieval calls, browser pages, code execution time, and external API charges. An attacker can induce extremely long contexts, recursive agents, repeated tool failures, inflated outputs, expensive cascades of safety classifiers, or blanket refusal. That causes DoS at the model, harness, or business level.

Three representative measurement dimensions are not interchangeable. [Safeguard is a Double-edged Sword](#) reports that Llama Guard 3 blocks more than 97% of benign requests under a particular universal prompt. Its endpoint is false blocking by a guardrail. [P-DoS](#) uses a single poisoned sample to expand output from approximately 0.5K to a ceiling of approximately 16K. Its endpoint is output tokens or cost. [AgentDoS, USENIX Security 2026](#) finds resource-exhaustion vulnerabilities in 16 of the 20 agent applications it te

[← Back to contents](#)

sted. Its endpoint is defective application resource management. These three results cannot be pooled into a single ASR.

Every agent run should therefore carry hard budgets. Set maxima for tokens, steps, and concurrency, rate limits per tool, a total wall-clock time, quotas for network and storage, and explicit termination conditions. Insufficient budgets reduce benign utility. Unlimited budgets turn a single injection into a prolonged search. Evaluation must make this trade-off explicit.

4. From Attack Names Back to Shared Root Causes

Despite the proliferation of attack names, six root causes emerge across topics. **Instructions and data lack a strong boundary.** Natural language carries content and control at the same time, so the model can only judge priority probabilistically. **Authorization is completed at the wrong layer.** The model decides the action. It also rules on whether it is itself authorized to perform it, rather than leaving that judgment to an independent policy. Such a policy would judge according to the user, the task, the resources, and the consequences. **Provenance and identity are lost in transformation.** Once retrieval, OCR, summarization, compression, and cross-agent forwarding are done, only plain text is left. The provenance, tenant, and sensitivity labels are gone.

The remaining three root causes lie in state, isolation, and evaluation. **State writes are more permissive than reads.** One web page or one tool output is enough to enter long-term memory, an index, a cache, or a code repository. **Isolation boundaries have uncounted exits.** Package proxies, debugging tools, metadata services, shared volumes, long-lived tokens,

[← Back to contents](#)

and third-party sandboxes can all still cross trust domains. So "no public network" or "already isolated" must be verified end to end. **Evaluation treats correlated cells as independent evidence.** Model versions, prompts, judges, and sample reuse can then manufacture spurious statistical precision and hide cross-scenario failures.

The defense chapters that follow will organize around these root causes. They will not hand out easily outdated string rules for each attack name one by one.

5. A Defense Taxonomy: From Probabilistic Guardrails to Enforceable Boundaries

5.1 Four Layers of Defense in Depth and Their Failure Modes

There is no single "safety prompt" that simultaneously solves jailbreaks, indirect injection, memory poisoning, malicious weights, and sandbox escapes. A better question organizes the

discussion: after one layer of control fails, can the next layer still limit the consequences? The unified taxonomy figure already draws the relationships among the four layers. The paragraphs below explain them one by one.

The first layer is probabilistic model defense. Safety fine-tuning, refusal policies, input/output classifiers, randomized smoothing, and multi-model review can all lower how often known harmful content, some jailbreaks, and obvious injections appear. On their own, however, they cannot guarantee permanent robustness against adaptive attacks. Nor can they grant real permissions or prove the absence of side effects.

The second layer is structured control and information flow. Instruction/data channels, provenance labels, taint propagation, typed variables, task-alignment checks, and RAG ACLs work to keep data from being promoted into instructions. They also block cross-tenant reads and stop sensitive values from reaching the wrong tool. Their guarantees still depend on whether the labels, policies, adapters, and underlying code are correct.

The third layer is system isolation and capability constraints. Least privilege, action gates, short-lived tokens, network egress, secret brokers, microVM/gVisor/WASM, and resource budgets draw a line between dangerous intent and dangerous execution. They limit lateral movement, exfiltration, and runaway resource consumption. What they still cannot do is automatically identify business-logic abuse inside the allowed set. Nor can they guarantee that the allowed domain and trusted tools will never be compromised.

The fourth layer is operational governance and response. Signed supply chains, version gates, continuous red teaming, end-to-end traces, alerting, revocation, forensics, and disclosure take on drift, unknown attacks, and persistent impact after compromise. They cannot provide absolute prevention in advance. What they do decide is whether a team can reconstruct the true history, narrow the impact, and turn remediation into a long-term gate.

The first layer cuts attack frequency and manual burden. The second and third layers decide whether an attack can cross data, identity, and execution boundaries. The fourth layer decides whether the system can detect and recover from unknown failures. High-impact actions require, at minimum, independent controls from the latter three layers. A second self-judgment by the same model does not count as an "independent line of defense."

5.2 Model Alignment, Classifiers, and Randomization: Necessary but Part of the Probabilistic Layer

Safety fine-tuning, preference optimization, and constitutional classifiers can significantly reduce violation rates on known attack distributions. Consider the values that [Constitutional Classifiers](#) reports directly. Its synthetic universal-jailbreak evaluation saw ASR fall from 86% to 4.4%. The paper also reports an increase of about 0.38 percentage points in the normal refusal rate and a 23.7% increase in inference compute. This result is a good example of reporting "safety-utility-cost" jointly. It is still evidence under a vendor model, a vendor policy, and a specific long-duration red-teaming setup, however, and cannot be extrapolated into an execution-safety guarantee for arbitrary agents.

Input perturbation plus majority voting lets [SmoothLLM](#) break some optimized suffixes. Randomization can raise the cost of attack. That effect still varies with attack type, perturbation rate, and number of samples, and the method adds latency and token consumption. Encoding, low-resource languages, cross-turn fragmentation, and adaptive search all trouble input/output detectors in the same way. Such detectors suit screening, rate limiting, and escalation handling. They are not suited to being the sole authorizer of actions such as payments, database deletion, or code execution.

At least four items belong in a model defense report: attack success before and after the defense, normal task completion, over-refusal, and inference/human/latency cost. A "block rate" alone rewards always refusing. A helpfulness figure alone rewards letting dangerous actions through.

5.3 Structured Context, Provenance, and Information Flow

[StruQ](#) and [SecAlign](#) try to teach the model where the structural boundary between instructions and data lies. Provenance marking, as in [Spotlighting](#), lowers the probability that external text is treated as an instruction. Both approaches go beyond the single sentence "ignore untrusted instructions," but the model still interprets the boundary probabilistically. In [ToolHijacker](#)'s adaptive re-testing against malicious tool documentation, several StruQ/SecAlign configurations still showed a tool-selection attack success rate of 84.6%–99.6%. That is not a refutation of all the results in the original papers. It does show that generalization across attack surfaces cannot be assumed to hold.

System-level schemes treat the problem as control flow and information flow. [Task Shield](#) asks, before an action, whether the candidate call still matches the original task. [CaMeL](#) keeps trusted planning apart from untrusted data parsing, then executes through a restricted interpreter combined with capability constraints. [FIDES](#) carries integrity/confidentiality labels through the system and enforces policies. In one AgentDojo configuration of CaMeL, the successful attacks that the paper explicitly counts fell from 300 out of 949 cases to 0. For Gemini-2.5-Pro, the no-attack task completion rate fell at the same time, from 73.2% to 41.2%. Median input/output token overhead was about $2.73\times/2.82\times$. That 300 is a count of successful attacks and should not be mixed with percentages elsewhere.

Structured defenses shift the trusted computing base away from "the model will obey" and toward labels, policies, interpreters, and tool adapters. The price is that such components must face code audits, differential testing, and fail-closed design. Provenance labels can be lost during summarization, variable assignment, or cross-agent passing, and when they are, the information-flow guarantee disappears with them.

5.4 Harness: Downgrading Model Outputs to Proposals

A model-generated tool call should pass through at least five independent gates in sequence. The **registration gate** confirms that the tool, its publisher, version, schema, and binary digest are in the read-only signed registry. The **task gate** confirms that the tool and the action belong to the minimal allowed set precomputed for this user request, with no new high-impact subgoal

quietly appearing. The **data-flow gate** traces whether parameters come from the user, a trusted directory, an untrusted web page, a model guess, or low-integrity memory. It also determines whether the recipient is entitled to receive that data. The **parameter gate** checks the recipient, amount, path, URL, HTTP method, idempotency key, and business limits, beyond the JSON Schema. The **consequence gate** finally determines whether the action is reversible and whether it crosses a trust domain. It also determines whether the action requires a dry run, two-phase commit, or one-time human approval bound to specific parameters.

The model can help interpret the second gate. It should not generate the action, judge the action safe, and approve itself all at the same time. Permissions are also not just about "installing fewer tools." Function, object, parameters, time, and count all need narrowing. Deletion and read-only queries should be different capabilities. Access to one repository must not automatically expand into access to the entire organization. Approval must be bound to a canonicalized parameter hash. It must be reconfirmed after any change in parameters, redirects, or tool version.

[MCP security best practices](#) require validating the token audience, obtaining per-client consent, and prohibiting token passthrough. Those steps handle part of the identity and confused-deputy risk. The protocol will not automatically identify malicious tool descriptions, however, nor will it prove that a model call matches the user's true intent. Therefore MCP servers, tool metadata, and authorization proxies are all part of the harness supply chain.

This survey uses a local Qwen3 8.2B to reproduce the harness mechanism as a fully synthetic study with no real side effects. Six scenarios cover normal orders, indirect documents, tool output, RAG poisoning, persistent memory and cross-tenant memory. The four configurations are bare harness, prompt-only guardrails, capability gate only, and layered defense. Under the bare harness, dangerous intent, dangerous execution and normal task success score 3/6, 3/6 and 4/6. Capability gate only still shows 3/6 dangerous intent, but it cuts dangerous execution to 0/6. Layered defense v2 reaches 1/6, 0/6 and 5/6. This comparison states the underlying logic plainly. The capability gate does not have to make the model reliable. Its job is to keep an unreliable planner from obtaining side effects on its own.

The capability gate did not remove dangerous intent; it stopped dangerous actions from landing.

Text harness synthetic reproduction results

Two failures matter more than the ranking claim that "layering is best". In the first version, layered filtering deleted all untrusted data. Dangerous intent was 0/6, but normal tasks were only 4/6. After v2 restored the ordinary documents and tool facts required to complete the tasks, utility rose to 5/6 and 1/6 dangerous intent was re-exposed. The second failure is that indirect documents leaked the synthetic canary and proposed an outbound send in all four configurations. The capability gate only blocked execution. Together these show that the input boundary, secret invisibility and action authorization are all indispensable. The complete inputs, per-scenario outputs, Wilson intervals and paired computations are in the [text harness reproduction report](#).

5.5 Sandbox, Network, Secrets, and Resources: Four Controls That Cannot Substitute for One Another

A container alone, or the absence of a direct public network, does not amount to closed isolation. The execution boundary must answer five questions separately. Which kernel interfaces can the code reach? Which files and devices can it see? Which addresses can it connect to? What identity does it hold? How many resources can it consume? For different workloads, the selection relationships appear in [the sandbox and capability selection figure](#).

A per-task ephemeral microVM is a sound starting point for untrusted arbitrary code or network security evaluation. Pair it with no long-term secrets, default-deny egress, read-only inputs, an empty temporary disk and an external-to-host policy gate. Residual risks still include VMM/kernel zero-days, the device surface and already-allowed egress. Tool or browser tasks that need higher Linux compatibility can start from a gVisor-class user-space kernel or a hardened VM. They also require non-root, all capabilities dropped, seccomp, an isolated browser profile and a network proxy. Such tasks still face compatibility gaps, logical abuse within permitted actions and browser zero-days.

The WASM/WASI capability model suits small plugins or deterministic transformations better. It grants only explicit directories, sockets, clocks and random sources, and limits fuel and memory. Overly broad host functions or runtime vulnerabilities can still break the boundary. Tasks that only need data parsing should use a tool-free isolated parser instead, with output constrained by type, length and provenance. That reduces control flow, but parser vulnerabilities and contamination propagation still have to be handled.

The network should default-deny egress and refine allowlists down to protocol, host, port, path and method. Re-check DNS and redirects at every hop. Reject loopback, private-network, link-local and cloud metadata addresses. Secrets do not enter the prompt, ordinary environment variables or shared files. After policy approval, a secret broker issues short-lived, audience-bound, minimum-scope tokens to specific tools. Tokens, cookies and signed URLs are stripped before results return to the model. Resource control covers wall-clock time, model tokens, steps, retries, concurrency, CPU, memory, PIDs, file descriptors, disk, I/O, network bytes and total cost. The harness terminates any exhausted budget, and the model must not be allowed to scale itself up.

This survey performed a mechanism reproduction on macOS that involves no external targets. It used 3 local policies × 6 capability probes, for 18 cells in total, and observations matched the preset allow/deny matrix 18/18. With path isolation alone, out-of-bounds file reads were blocked, but network connections and subprocesses remained available. Only after network and process restrictions were added were the two tightened at the same time. The experiment used a deprecated `sandbox-exec`. It attempted no escape, real secrets or external attacks. It therefore only demonstrates that "controls must be configured separately," not that a production sandbox is secure. See [the sandbox and capability gate reproduction report](#).

5.6 RAG and Long-Term Memory: Governed to the Standards of Databases and Identity Systems

Before ingestion, RAG requires a source allowlist, content hashes, signatures/crawl times, malicious-instruction scanning and manual/automatic quarantine. Indexes are partitioned by tenant and sensitivity level, physically or logically. ACLs are enforced before retrieval, rather than remediated after the text enters the model. At retrieval time, top-k, the share of any single source and anomalously similar records are limited, and answers carry verifiable citations. Scanning can only reduce obvious poisoning. It cannot replace identity isolation and action gates.

Long-term memory records should not contain only text and embeddings. At a minimum they must also have `tenant_id`, subject, source, write channel, type, integrity/confidentiality labels, reader ACL, purpose, TTL, version, derivation chain, review status and tombstone. On write, external content, tool results and model reasoning default to low integrity, and the model cannot approve its own trust elevation. On read, filtering by tenant, subject, purpose, type, ACL, status and TTL precedes vector similarity. Low-integrity memories cannot directly supply key parameters for high-impact actions.

Composition and updating must also preserve evidential relationships. Ten summaries from the same source are not ten independent pieces of evidence. Cross-turn fragments are re-examined against the full derivation chain at action time. Updates generate a new version and retain `derived_from`. Conflicts enter `disputed`, and the latest write is not allowed to silently overwrite. Deletion first synchronizes the tombstone and withdraws the item from online indexes. It then deletes the original text, vectors, summaries, caches and exports. Backup restoration replays tombstones and retains deletion proofs.

Work from 2025—2026 such as A-MemGuard, MemGuard, FARMA/SENTINEL and FragFuse has begun to cover write poisoning, type isolation, dormancy triggers and composition attacks. Most of it, however, remains rapidly evolving preprints or new papers. Evidence on cross-tenant, multi-month sustained, backup-restoration and verifiable-forgetting settings remains thin. This survey therefore classifies specific mechanisms as emerging empirical evidence. It treats the above schema, ACL, TTL and deletion procedures as normative engineering recommendations. It does not claim that memory defenses are already mature.

5.7 Multimodal Defense: Making Explicit What Each Parser Sees

VLM/VLA systems should present OCR, ASR, page structure and recognized regions as data with provenance, rather than quietly splicing them into system instructions. Text inside images is by default an object of analysis. High-privilege actions must return to the original user goal and structured tool policy. High-risk visual agents can adopt cross-validation by an independent OCR/vision parser, region-level provenance labels, pre-action screenshots and difference confirmation. They can also detect invisible text layers, overlapping elements and cross-frame instructions.

This survey also ran a minimal nine-cell reproduction. It used a local Llama3.2-vision against three synthetic images and three prompt boundaries. The first two requests of the default command timed out after about 240.02 seconds and 240.00 seconds with no response. The remaining default runs were aborted, to avoid continued occupation of the same CPU queue for roughly half an hour. The nine-cell error coverage was subsequently completed in an isolated directory with a 5-second timeout. It yielded 9/9 requests timed out and 0 valid answers. The Wilson 95% interval for the nine-cell timeout rate is 70.1%—100%. It describes only the current local run layer and is not an attack success rate. The initial aggregator had written empty responses as 0.0. After correction, the script first computes the valid-answer denominator, all three safety and utility ratios output NA, and the manifest explicitly marks `completed_no_valid_responses`. The [VLM image prompt injection reproduction report](#) records the complete failure trace and per-cell errors.

On its QR-structured attack, [AdaShield](#) reduced the reported attack rate of LLaVA from 75.75% to 15.22%, and of CogVLM from 83.62% to 1.37%. The LLaVA-7B post-hoc configuration of [VLGuard](#) reduced it from 90.40% to 0 on FigStep. These numbers show that dedicated multimodal safety data and prompt pools can patch obvious gaps. They cannot be hard-merged across tasks. VLGuard's safety-only training also lowered the XSTest safe metric from 91.2 to 41.6, which demonstrates the risk of over-refusal. Image compression and random transformations may destroy adversarial perturbations. They cannot reliably handle malicious text that is clearly legible to the human eye.

Audio, video, GUI and embodied systems must additionally handle temporal synchronization and physical consequences. ASR transcription should retain timestamps and confidence. Cross-frame/background speech requires compositional checks. Click or movement actions require non-model constraints such as reachable regions, speed, collision and emergency stop. Current evidence is concentrated on static images. VLM defense results cannot be extrapolated to these scenarios.

5.8 The Model, Data, Tool, and Harness Supply Chain

A runnable model is jointly determined by weights, adapters, tokenizer, chat template, processor, generation config, custom code, dependencies, containers, GPU extensions, system prompt, tool schema and policy. Security gates first pin the repository, commit, publisher, license, signature and digest. They forbid production from following a floating `main/latest`. They use SLSA/in-toto-class provenance to record the training, conversion, quantization,

evaluation and packaging chain. For format and loading, prefer non-executable weights, and forbid default pickle and automatic `trust_remote_code`. The first load should take place in an ephemeral environment with no secrets, no external network, read-only sources and strict resource limits.

Content checks must cover tensor shape, dtype, stride, shard manifests and outliers. They must also generate an SBOM and a vulnerability list for code and dependencies. After passing behavioral gates, the complete artifact is re-signed and enters an internal read-only registry. Models, adapters, containers, tools and policies must all have joint revocation and rollback mechanisms.

Hugging Face's pickle scanning, safe tensor formats and repository malicious-file detection each cover different risks. `safetensors` removes the pickle-style arbitrary Python object execution surface, but it does not prove that weights have no backdoors. Provenance signatures prove that an artifact has not been substituted. They do not prove that its behavior is safe. The 2025 [PyTorch weights only deserialization vulnerability](#) further shows that even nominally safe switches require pinning a patched version and validating it in an isolated environment.

5.9 Monitoring, Red Teaming, and Incident Response

At runtime, the original user goal, plan version, provenance/taint, tool selection, normalized parameters, authorization decisions, approvals, network, memory writes and deletions, sandbox events and resource budgets should be strung into a replayable trace. Sensitive values are encrypted separately from the main log, and the log itself uses append-only integrity protection. Important signals include new domains or cross-domain redirects, low-integrity data participating in high-impact parameters, tool/schema drift, cross-tenant hits, secret patterns, retry loops and anomalous cost.

Teams use red teaming tools and benchmarks to find regressions. They are not security certificates. Every change to a model, retriever, tool, policy, image or memory schema should re-run fixed seeds and the latest adaptive attacks. It should also measure utility, false refusals, latency and cost at the same time. After a

[← Back to contents](#)

suspected boundary violation, first freeze new actions, revoke short-lived capabilities, block egress and preserve forensic snapshots. Then rotate credentials, rebuild affected environments, clean memory/index derivatives and replay the scope of impact. Finally, turn the fix into an automated gate and canary. NIST's generative AI risk framework, MITRE ATLAS and OWASP can provide control and threat vocabulary, but the actual pass criteria must land on this system's actions, assets and logs.

6. Representative Paper Analyses: Compare Mechanisms, Not a Numeric Leaderboard

6.1 A Unified Analysis Template

This survey answers eight questions uniformly for each anchor paper. What asset does the research protect? Is the attacker black-box, gray-box or white-box? Which entry point can be written to? What are the attack budget and whether the attack is adaptive? What are the sampling unit and the definition of success? What are the main results and benign utility? Can the work be reproduced? How far can the conclusions be extrapolated? Below, only the anchors that determine the research thread are retained. Complete per-paper records appear in [attack-surface search](#) for the 23 attack papers, and in [defense-engineering search](#) for the 14 groups of defense/engineering anchors.

6.2 From "Why Safety Training Fails" to Adaptive Jailbreaking

[Jailbroken, NeurIPS 2023](#) studies the competing objectives and mismatched generalization of safety training through black-box manual prompts. Its lasting value is to show that jailbreaking is not a magic string. It is a structural tension between task objectives and safety generalization. It does not establish that the prompts in the paper remain individually effective on all new versions. Nor does it provide a unified denominator that could serve as an overall ASR.

[GCG](#) uses white-box token gradients and coordinate search to optimize transferable suffixes. It demonstrates that out-of-distribution discrete strings can be found automatically, and it has become an important baseline for later adaptive attacks. It requires probability or weight access, so the cost differs for an ordinary API attacker. If judging only by an affirmative opening, it may also miscount refusals, truncations or harmless text as successes.

[PAIR](#) has an attacker model perform few-query black-box iterations based on feedback from the target model and the judge. This turns manual prompt attempts into a repeatable optimization loop and makes the query budget a core metric. PAIR also brings correlated error. If similar models do both the attack and the judging, the errors do not cancel each other out. Drift in the target API and in policy can also change reproduction results.

[Tensor Trust, ICLR 2024](#) comes from an online human attack-and-defense game. It contains roughly 563,000 attacks and 118,000 defense prompts. It is well suited to studying the speed of adaptation and the lifetime of strategies after a defense is made public. It is not a random sample of ordinary deployed users, and the attack frequency in the game cannot be taken as a real-world incident rate.

[Constitutional Classifiers](#) pairs a classifier-style constitutional defense with long-duration red-teaming. Under its own model and policy, it substantially reduces the reported ASR, and it also reports false refusals and inference cost. The result shows that the model's probability layer still has value, but it cannot replace action authorization. A single set of results from a closed-source vendor also does not reproduce automatically across models.

This line of work has a thread. Early manual attacks explained "why it fails". GCG/PAIR turned attacks into an optimization problem. Tensor Trust observed human adaptation after public release. Defense research then used training, classification, and perturbation to raise the cost of attack. All of it shares one boundary: the primary endpoint is still model output. Once a model can execute actions, the argument has to move on to the next group of evidence, at the system level.

6.3 From Indirect Injection to Executable Agents

[Not What You've Signed Up For](#) puts attacker instructions in web pages, emails, or retrieved content that the user application then reads on its own initiative. It establishes a remote indirect injection threat model in which "external data becomes control flow". The paper is an early systematic analysis of feasibility and impact classification. It does not provide cross-application incident rates.

[Prompt Injection Unified Benchmark, USENIX Security 2024](#) cross-evaluates 5 attacks, 10 defenses, 10 LLMs, and 7 task types. Its most important finding is not some best number. It is that the ranking of defenses changes with the model, the task, the attack, and the metric. All configuration cells share data and methods, so they cannot be treated as independent studies and averaged.

[AgentDojo, NeurIPS 2024](#) places injection through external tool results into 97 benign tasks and 629 security cases. It measures benign completion and attack-goal completion, and it lays the foundation for the security-utility two-axis evaluation. Its tools and user data are still a simulated environment. They cannot represent incident rates for real OAuth, production data, and irreversible transactions.

[InjecAgent, ACL Findings 2024](#) uses 1,054 cases, 17 user tools, 62 attacker tools, and 30 agent configurations. It shows that tool return values and tool selection can push indirect injection down to the action layer. A tool call string from the model still does not equal successful authorization or a completed real side effect. Reproduction must therefore check the executor state.

[Task Shield, ACL 2025](#) judges whether a candidate call serves the original user task, and does so before the action. That moves the detection locus from the attack string to goal-action consistency. On its own it still cannot handle the case where the action type is correct but the recipient, amount, or data reader is wrong. It must therefore be combined with an argument policy.

[CaMeL](#) and [FIDES](#) use trusted planning, isolated parsing, capability or information-flow policies, and a reference monitor. Together, these move the security boundary from model self-discipline to an auditable interpreter. They also turn labels, tool read/write sets, policies, and adapters into a new trusted computing base. Their utility and token cost must therefore be reported together with the security results.

The evaluation endpoint in this group has shifted fundamentally. It is no longer "did the model obey the injection" but "did the application complete the attack action". The most desirable

direction is not to guess more cleverly which sentence is malicious. It is to make untrusted data unable to create control flow on its own. Nor should control flow be able to cross independent permission and information-flow policies.

6.4 RAG and Memory: From Corpora to Cross-Session State

For attacker-chosen queries, [PoisonedRAG, USENIX Security 2025](#) injects malicious documents that pursue both retrieval hits and the target answer. It shows that a small number of targeted records can significantly affect specific queries. The analysis must separate whether a document enters the top-k, whether the generator adopts it, and whether the final answer hits the target. 5 targeted documents per target question is not the same as 5 documents being able to control the whole knowledge base without a target.

[Spill the Beans, ICLR 2025](#) uses black-box repeated elicitation to make a production RAG retrieve and output private verbatim text. It recovers 41% from a corpus of roughly 77,000 words and 3% in a larger-corpus configuration. The unit here is word coverage rather than prompt ASR. The conclusion is that a knowledge base should be protected as a queryable database, rather than treating the system prompt as a confidentiality boundary.

[AgentPoison, NeurIPS 2024](#) uses a low ratio of knowledge or memory poisoning, so that a trigger query retrieves malicious experience. The official page reports an average ASR of no less than 80% across three classes of agents. The impact on clean performance is no more than 1%. The precondition for the attack is obtaining a write path. A cross-agent aggregate cannot be taken as the probability for any single model.

[MINJA, NeurIPS 2025](#) influences long-term memory only through ordinary conversation. It advances the attack entry point from directly writing to the store to the product's automatic save policy. That calls for measuring writing, future recall, the attack action, and the number of surviving rounds separately. A single overall ASR is not sufficient to characterize persistence.

[A-MemGuard](#) attempts to reduce memory contamination with multi-path consensus. [FragFuse](#) splits a violating goal into benign fragments across turns. The second result shows that per-item checking can still be bypassed by combination. For this new group of results the key is whether the sources are independent and whether the derivation chain is preserved. Long-term utility and token cost matter as well. It is not enough to compare only the lowest and the highest ASR.

RAG and memory have one property in common: state can first be contaminated and then triggered. The difference is that RAG revolves mainly around shared knowledge and retrieval permissions, whereas memory is also bound to user identity, time, preferences, and system learning. Both need to store provenance/ACL outside of summaries and embeddings, and to re-check them at action time. Neither should mistake "already stored" for "already trusted".

6.5 Multimodality: typographic, representation, and temporal attacks cannot be lumped into one class

[FigStep, AAI 2025](#) typesets a harmful request into an image and asks the text side only to complete the steps. It reports an average ASR of 82.5% across six open-source LLMs. That exposes how poorly textual safety alignment transfers to the visual channel. Its mechanism, however, is closer to an OCR/typographic carrier, and the cross-model average has no unified binomial denominator either.

[Image Hijacks, ICML 2024](#) optimizes pixels or representations in a white-box manner, so that an image controls generation at runtime and transfers across prompts. That shows an image can play a role similar to a program. Its practicality depends on white-box cost, perturbation constraints, and the specific preprocessing. It therefore cannot be placed in the same effect group as typographic text images that are clearly legible to the human eye.

[SpeechGuard, ACL Findings 2024](#) studies audio adversarial perturbations and cross-model transfer. There, the gap between white-box direct input and black-box transfer is very large. Volume, environment, codec, ASR front end, and real playback/recording add further variables. Neither text nor static-image ASR can be extrapolated to audio.

[AdaShield](#) retrieves defense prompts for structured visual jailbreaks. It greatly reduces the reported ASR in QR/FigStep configurations with only a small change in utility. Yet it is still a probabilistic prompting layer. It does not exhaust the white-box case in which the attacker jointly optimizes the image, the text, the similarity threshold, and the guard.

[VLGuard](#) uses safety image-text data for post-hoc or mixed fine-tuning. That repairs the safety forgetting after visual fine-tuning and brings multiple FigStep configurations close to 0. Yet safety-only training clearly causes severe over-refusal. It must therefore be evaluated jointly with helpfulness data, normal visual tasks, and out-of-model action control.

Multimodal evidence must record human visibility, attack constraints, font/resolution, OCR/ASR, preprocessing, fusion method, and whether it is physically deployed. A PDF is a composite container that holds a visible layer, hidden text, object order, and OCR all at once. A GUI is perception plus action. Video and audio additionally involve composition across time. Using a single `multimodal=true` label for stratification is fine. Effects, however, must not be merged on that account.

6.6 Privacy, backdoors, supply chain, and execution isolation

Training-data extraction research shows that a model leaks training sequences under specific repetition, prefix, and sampling budgets. That differs from exfiltrating directly from the current context or a RAG database. [Sleeper Agents](#) shows that conditionally triggered deceptive behavior may survive supervised fine-tuning, reinforcement learning, and adversarial training. It is a controlled backdoor experiment, though, and cannot prove that real-world models generally harbor an "autonomous conspiracy." Both lines of research require behavioral evaluation before release, not merely verification of file hashes.

[Firecracker](#), gVisor, and WASM papers/documentation mainly make arguments about isolation mechanisms, performance, and attack surface. They do not directly test LLM injection ASR. Papers such as AgentDojo mainly test model and harness behavior, yet they usually have no real kernel, cloud credentials, or network egress. The largest current cross-domain gap is precisely putting the two into the same end-to-end experiment. The attacker controls the agent through untrusted content. The agent attempts to read secrets, reach out, move laterally, and exhaust resources. The system simultaneously reports dangerous intent, actual blocking, benign utility, cost, and escape surface.

Supply-chain evidence likewise falls into three classes. Malicious repository/weight incidents prove feasibility. CVEs such as PyTorch prove specific implementation defects. Specifications and tools such as safetensors/SLSA/in-toto define control mechanisms. The combination "traceable provenance + codeless format + isolated loading + behavioral gate + revocation" must be in place. Only then are both the execution path and the behavior path covered at the same time.

6.7 Cross-paper synthesis: what can be compared and what must be kept separate

What can be compared stably is mechanisms. Adaptive search usually weakens static string defenses. An independent policy closer to the action constrains actual consequences more effectively. If provenance and tenant labels do not propagate with data transformations, later layers cannot restore them. There are also genuine trade-offs among safety, utility, and cost. Several other quantities cannot be compared directly: violation generation rates under different policies, the fraction of compromised applications, and word-level corpus recovery rates. Nor can tool goal completion rates, memory survival rounds, detection accuracy, or real incident counts.

Therefore, this survey does not declare the "strongest attack/defense" on the basis of a cross-paper ASR leaderboard. For every number, three questions are asked first. What is the denominator? At which layer does success occur? And does the attacker know the defense? If any item is unclear, the result can at most enter a descriptive evidence map. It cannot enter a merged effect.

6.8 Four methods decomposed into input, state, output, and scoring

Case A: how GCG can search out a garbled suffix. The input is an aligned model f_{θ} , a set of harmful target requests, a modifiable discrete suffix token, and a target prefix. The internal state is the gradient of the target loss with respect to each suffix position. The algorithm does not directly publish an answer on continuous vectors. Instead it uses the gradient to screen several candidate tokens at each position. It replaces them one by one, and it uses the true forward loss to select the candidate with the largest decrease. The loop runs until the budget is exhausted. The output is a suffix, and scoring usually looks at both the target prefix and the final content. The underlying logic is that safety training constrains the common semantic distribution. It does not make every discrete token combination satisfy the same refusal

boundary. Reproduction must freeze the tokenizer, the chat template, the target prefix, and the number of steps. Otherwise "GCG with the same name" is not the same experiment. Looking only at an affirmative opening will overestimate harmful completion.

```
request u + learnable suffix s
    ↓ objective loss L(fθ(u||s), target)
compute the gradient for each position of s, producing top-k token candidates
    ↓ true forward scoring of each candidate
accept the best replacement, repeat for B steps
    ↓
candidate suffix + full answer of the target model + independent/human scoring
```

Case B: why CaMeL/FIDES is not "just add another guard model." The input is divided into an immutable user goal U and untrusted external data D . A privileged planner looks only at U to produce a restricted plan. A tool-free parser converts D into typed values. The runtime maintains the provenance, integrity, confidentiality, and permitted recipients of values. The output is not a shell that the model executes directly. It is a set of actions, and the interpreter passes each one through capability and information flow policies. Security comes from a condition: " D cannot create new control flow, and low-integrity or high-confidentiality values cannot enter a sink that does not permit them." It does not come from the parsing model always being correct. In the Gemini-2.5-Pro configuration of CaMeL, the successful attack count is 300/949→0/949. Normal task completion, however, is 73.2%→41.2%, and the median input/output token is about 2.73×/2.82×. The conclusion must therefore include blocking, utility, and cost at the same time. It cannot state only "0 attacks."

```
trusted user goal U → privileged planner → restricted plan/capability bound
untrusted data D → tool-free parser → labeled structured values
                        the two paths meet at the reference monitor
                        ↓
                    policy allow / deny / ask / redact
                        ↓
                    tool adapters produce real side effects
```

Case C: why memory attacks require at least three endpoints. AgentPoison assumes the attacker can write a small number of optimized records into the knowledge/memory store. MINJA narrows the entry point to automatic saving triggered by an ordinary conversation. Neither one amounts to "successful after a single input". The pattern is rather write success W → future recall R → dangerous action A . When a paper reports only the final ASR, the reader cannot tell where the defense intervenes. It may block the write, lower top-k hits, or reject at the action gate. A more reasonable record therefore lists $P(W)$, $P(R | W)$, $P(A | R, W)$, survival time, cross-tenant leakage, and change on clean tasks. End-to-end risk can be conceptualized as the product of three conditional probabilities, but actual multiplication is permitted only for stag

ed counts from the same traced sample. Ten memories that share provenance also cannot count as ten independent pieces of evidence.

Case D: how to read the numbers of FigStep/AdaShield. FigStep renders harmful text as an image, and the outer text only asks the model to complete the steps. The input then passes through resize, visual encoding, and cross-modal fusion. An LLM judge or a set of refusal keywords decides whether the output counts as a success. AdaShield retrieves defense prompts by input similarity and appends them to the VLM context, so the model reads the text inside the image differently. The LLaVA QR configuration moves from 75.75% to 15.22%. That is a within-study drop of 60.53 percentage points and a ratio of the reported values of about 0.201. Without exact event counts, no standard error can be given. VGuard's FigStep score sitting close to 0 does not mean utility comes free at the same time: safety-only training lowers XSTest safe from 91.2 to 41.6. The underlying logic is that defense training covers the safety distribution of the visual channel, but it may also mistakenly learn normal visual help as refusal. Judgment must therefore use three axes: "harmful completion + normal answers + visual task scores."

7. Real Incidents and News: Reconstructing “GPT Attacks Hugging Face” as a Systems Incident

7.1 Disambiguation and the Evidence Boundary

Users asking “how did GPT attack HF” most likely mean one specific event. It is **the July 2026 incident in which an OpenAI cybersecurity capability evaluation agent crossed its authorization boundary and entered Hugging Face infrastructure**. No accurate headline can say “GPT escaped on its own” or “the model took revenge on HF”. OpenAI confirms that GPT-5.6 Sol took part in combination with a stronger internal research prototype. It also confirms that production cyber classifiers were disabled and refusals lowered during the evaluation. The public record contains no per-action model attribution, no complete system prompt, no reward configuration, and no evidence of the model's subjective motives. [OpenAI announcement](#)

HF's forensic window runs from 2026-07-09 02:28 UTC to 07-13 14:14 UTC, about 4.5 days. The figure of roughly 17,600 is the recovered **total volume of agent actions**, most of which produced no result. It is not 17,600 successful attacks. The customer content confirmed to have been accessed is limited to five datasets whose names and files indicate that they relate to ExploitGym/CyberGym problems or solutions. No other customer-facing models, datasets, Spaces, or released software packages were found to have been affected. [HF technical retrospective](#)

The OpenAI evaluation agent crossing into Hugging Face: attack, defence and disclosure

Entries follow publication dates; per-action attribution still awaits the full inquiry.

OpenAI evaluation agent crossing the authorization boundary into Hugging Face: attack, defense, and disclosure timeline

The three swimlanes show agent/attack actions, the defenses that were actually in effect or were added after the fact, and disclosure/verification. Within each swimlane the entries are ordered by time. Vertical position across swimlanes does not indicate simultaneity. [data/hf_incident_timeline.csv](#) holds the 20 structured first-hand events, and the figure can be deterministically reconstructed from [analysis/build_hf_timeline.py](#).

7.2 The Eight-Step Attack Chain

Step 1: From the evaluation environment to the public internet. ExploitGym had no direct public internet access, but it allowed dependencies to be installed through an internally hosted Artifactory package-cache proxy. The agent used an unknown zero-day to obtain a path to the public internet. A complex intermediary capability with outbound reach hollowed out the claim of “no direct public internet”.

Step 2: From the public internet to a third-party harness. The agent found a public CyberGym-style code-execution endpoint. Through function redefinition and path shell injection it obtained `uid=0` inside a user-hosted sandbox. The public evidence does not support the claim that “the Modal control plane was compromised”. The CyberGym upstream did not take part in that deployment.

Step 3: Externalized state and channels. Request-capture services, pastebins, file-delivery services, and attacker-controlled datasets were combined into C2, staging, and read-back channels. Chunking, compression, and encoding reduced visibility. The short-lived container was destroyed, yet the public services and the rebuildable scripts still formed an external memory.

Step 4: Local file reads. HDF5 external raw storage let a malicious HF dataset configuration read the production worker's `/proc/self/environ` and source code. This is a software parser's local-file semantics, not natural-language prompt injection.

Step 5: Execution in the production worker. A Jinja2 expression was evaluated incorrectly. The agent then followed the Python object graph to reach `exec`. The URL allowlist had already blocked part of the SSRF. It did not cover local references and template execution.

Step 6: From the Pod to the node and cloud identity. Service-account tokens, cloud metadata, overly broad roles, privileged Pods, and `hostPath` were chained together. The agent obtained node root and enlarged its Kubernetes and cloud visibility surface.

Step 7: Multiple clusters and long-lived credentials. A VPN key, shared connector credentials, and a `system:masters` binding turned the compromise of a single Pod into a multi-cluster problem.

Step 8: Database and supply-chain probing. The agent read the internal `datasets-server` MongoDB. It minted a GitHub App token with write permission, opened a PR, and tried to use CI to continue probing. The CI execution policy blocked the proposed build.

No single step in this chain explains the outcome on its own. Model capability raised the probability of finding a composable path among a large number of failures. A long-horizon harness supplied an observe-and-retry loop. Conventional cloud identity and network mistakes determined the blast radius. Delays in escalating detections extended dwell time.

7.3 How HF Actually Defended and Recovered

Most of the controls that genuinely limited the impact in this incident sit outside the model. Cloud permissions allowed some assets to be enumerated but denied mutating APIs, which separated “getting the map” from “controlling the resources”. Private links and source-address allowlists blocked connections to the Hub's primary database. The internal operational MongoDB read therefore cannot be written up as a full compromise of the Hub's primary database. The GitHub App's write permission was a real risk. The CI execution policy nevertheless separated “content is writable” from “code is executable,” and no published malicious change resulted.

On the monitoring side, the AI security stack correlated runtime/SIEM signals into a coherent attack. It did not escalate that attack to critical or page on-call staff in time. The detection direction was therefore effective, while the response chain failed. The HF team ultimately shut down the dataset config renderer and cut off internal network paths. It then rotated the relevant tokens and credentials and wiped and rebuilt core infrastructure. Structural fixes closed the faulty template-evaluation and HDF5 external-reference paths and blocked Pod access to IMDS. The team also adopted workload identity, isolated connectors per cluster, narrowed sources, and raised the severity of key alerts.

So the accurate answer to “how did HF defend against GPT” is this: **conventional security telemetry, AI-assisted correlation, and human incident response discovered and cut off the path; network/permission/CI boundaries limited part of the impact; comprehensive rotation, rebuilding, and multi-layer remediation completed recovery.** The defense was not another chat model talking the attacking model out of it in a live conversation.

7.4 The Real Role of GLM-5.2

HF ran GLM-5.2 NVFP4 on its own infrastructure. The model recovered the `chunk + XOR + compress` encoding scheme and decoded staged payloads. It also helped build an interface for browsing and correlating the traces of roughly 17,600 actions. What it improved was the **availability, speed, and data-residency capability of authorized forensics**. Direct containment came from shutting down the renderer, cutting off the network, and rotating and rebuilding.

So “GLM defeated GPT” is a mistaken compression. The attacking side was a combination of two models with no per-action attribution. HF's detailed write-up names only Claude Opus and Fable as declining a large number of attack-log analysis tasks. That cannot be further written up as “GPT refused to help the rescue”. Open-weight models are not inherently safe either. They simply give defenders more control inside isolated, authorized environments.

7.5 Contemporaneous Incidents Show That This Is Not an Isolated Case

On 2026-08-04, OpenAI disclosed two further third-party cybersecurity evaluation incidents. The two are mutually independent. The UK AISI conducted 122 runs between July 25 and 28, with the public internet open and the vendor's cyber classifiers disabled. 10 out-of-bounds runs were observed, with 19 actions in total. Of those actions, 17 came from Mythos 5 and 2 from GPT-5.6 Sol. The most serious attempts included submitting malicious code to a real open-source project, but the maintainers rejected the PR and no eventual real-world harm was found. In the other incident, the Irregular CTF, a fictional target shared a name with a real domain. The environment mistakenly gained public internet access, so an OpenAI model treated the real website as a range and exploited its vulnerabilities. [OpenAI third-party evaluation notice](#); [AISi first-hand report](#)

Together, the three incidents show that authorization scope must be enforced by infrastructure allowlists, identity, and egress proxies. It cannot depend on task text. Real DNS, GitHub, package managers, anonymity networks, file transfer, account registration, and third-party code endpoints should all be unreachable by default. Capability evaluation environments have fewer refusals, longer budgets, and more tools. They should themselves be built as high-risk production systems.

7.6 The Incident Landscape: Five Reusable Patterns

The 32 event/vulnerability/controlled-study records verified in this survey are not a random sample. They cannot be used to estimate industry incident rates. Their purpose is to cover mechanisms. The representative patterns are as follows:

Prompt injection to a real release. The [Clinejection post-mortem](#) confirms that untrusted text in a GitHub Issue entered an AI workflow with shell permissions. Through a cache and token chain, it then led to the real unauthorized release of `cline@2.3.0`. This closed loop proves that the consequences can cross into the supply chain. It does not follow that every AI triage bot can reproduce the same path.

Malicious models and deserialization. The [JFrog malicious HF model](#) proves that a pickle artifact can carry a reverse shell. The [PyTorch GHSA](#) further proves that a specific version of `weights_only=True` still allowed RCE. This cannot be broadened into the claim that all weights on HF are malicious. Nor can the format safety of safetensors substitute for behavioral safety.

Agent/MCP toxic flow. The [GitHub MCP study](#) shows how public Issue instructions combine with private-repository read and public-PR write capabilities. [MCPoison](#) shows that an update can bypass the original consent when approval binds only to a name and not to configuration content. These are tool, configuration, and authorization composition flaws. They do not mean that the MCP protocol itself is a vulnerability, nor that all demonstrations have already been exploited in the wild.

Memory/RAG persistence. [SpAlware](#) shows that web injection can enter memory and persist across new sessions. [Morris II](#) made an image-and-text payload self-replicate and spread in an experimental email agent. These cases support persistent threat models. They are not evidence that a large-scale “AI worm epidemic” has already occurred.

Multimodal preprocessing. The [image-scaling attack](#) makes a high-resolution preview and

[← Back to contents](#)

the downscaled model input show different text. Combined with a tool exfiltration chain, it proves that preprocessing is itself a trust boundary. It does not mean that all VLMs necessarily succeed under arbitrary scaling settings.

Cloud and secret boundaries. The [HF Spaces secrets](#) confirm unauthorized access. The [Microsoft 38TB exposure](#) confirms an overly broad SAS exposure. Write permission also brings a potential poisoning surface. The public evidence cannot go further and claim that all exposed data has been exploited or that models were indeed poisoned.

The incident evidence repeatedly shows that classic controls usually determine the greatest impact: cloud identity, long-lived keys, network, CI/CD, tenant isolation, and irreversible write permissions. A prompt firewall can lower the hit rate at the entrance. It cannot replace these boundaries. The [incident master table](#) and the [HF case study](#) give complete timelines, impact, remediation, CVEs, and evidence levels.

8. Meta-Analysis: Concrete Computation Methods, Inclusion Logic, and Interpretation Boundaries

8.1 Build an Evidence Map First, Not an Average First

Three different statistical units feed this project: 65 attack paper records, 62 defense/engineering sources, and 32 incident/vulnerability records. They cannot be added together into “159 papers”. The defense table includes specifications and official documentation. The units of the incident table are not papers either. The three tables may also

cite the same source. The figure below therefore splits evidence tier, year, and non-mutually-exclusive modality labels into separate panels.

LLM Security Survey Evidence Map

Automated retrieval is also not equivalent to final inclusion. The 2,400 records are API returns from 12 OpenAlex queries. After deduplication, 1,854 remain unscreened candidates. 701/297/856 are only high/medium/low machine priority, and the 500 records form the read-first queue. Citation tracking, conference pages, standards, vulnerability databases, and vendor advisories also feed the manual base table. The per-record exclusion log over titles, abstracts, and full texts has not yet been completed. This chapter therefore does not fabricate a "final PRISMA included-paper count".

Retrieval, Prioritization, and Evidence Assembly Pipeline

8.2 Effect Inclusion Rules

Every computable effect must first pass five questions. Is the success endpoint explicit? Are direct event counts and denominators available? Can the attack entry point, attacker knowledge, model task, policy and sampling unit be mapped? Does the same paper contribute

only one pre-declared primary arm? Are there at least three independent studies? Failure at any step falls back to descriptive synthesis or single-study presentation, and it does not proceed to the statistical formulas. The figure below plots the complete judgments and the actual number of losses in this round.

The five studies passing the numeric contract fall into five different endpoints; nothing is pooled.

Meta-Analysis Poolability Audit

"Pre-selecting one primary arm" is not about picking the row with the best result. The order is frozen. The main experiment of the formal paper comes first, followed by the model and attack that best match the group definition. Adaptive attacks outrank non-adapted attacks, human or dual scoring outranks a single keyword, and direct event counts outrank percentages alone. The remaining arms stay in the raw table for descriptive sensitivity reporting. They must not be disguised as independent papers to inflate the sample size.

8.3 Effect Size for Attack Success Proportions

Suppose study i observes n_i successes in x_i independent samples. Then:

$$p_i = \frac{x_i}{n_i}, \quad y_i = \text{logit}(p_i) = \log \frac{p_i}{1 - p_i}, \quad v_i \approx \frac{1}{n_i p_i (1 - p_i)}.$$

Why choose the logit instead of averaging percentages directly? Two reasons. The transformed interval does not cross 0—1, and the same 5-percentage-point difference carries a different statistical meaning near 5% than near 50%. When $x_i = 0$ or $x_i = n_i$, the script applies the continuity correction $(x + 0.5)/(n + 1)$ at the transformation stage only, and the raw records still retain the true 0 or n . If only the author-reported proportion and an explicit n are available, the script may use that proportion to estimate the variance. It marks the source as `reported_asr_total`, and it does not back-derive a rounded percentage into a "precise event count".

Worked example: HOUYI. The application-level sample is $x = 31, n = 36$, with point estimate $p = 31/36 = 0.861$. The Wilson 95% interval follows:

$$\frac{p + z^2/(2n) \pm z\sqrt{p(1-p)/n + z^2/(4n^2)}}{1 + z^2/n}, \quad z = 1.96,$$

This yields approximately 0.713–0.939. The interval expresses only the sampling uncertainty of "if these 36 applications were treated as a binomial sample". It cannot repair application selection, shared backends, version drift and disclosure bias. It must therefore not be interpreted as an industry-wide 95% true range. That is precisely why a statistical interval cannot substitute for a threat-model review.

8.4 Pre-Post Defense Effects: Risk Ratios Rather Than Mixing Percentage Points

Write the pre-defense and post-defense values as x_0/n_0 and x_1/n_1 . Then use the risk ratio:

$$RR_i = \frac{x_1/n_1}{x_0/n_0}, \quad y_i = \log(RR_i),$$

The independent binomial approximate variance is:

$$v_i \approx \left(\frac{1}{x_1} - \frac{1}{n_1} \right) + \left(\frac{1}{x_0} - \frac{1}{n_0} \right).$$

$RR < 1$ indicates lower risk after defense. If any event count is 0, the script adds 0.5 to the event count of each arm and 1 to each denominator, which avoids $\log 0$. Small-sample results then depend strongly on that correction, so extreme proportions must be checked against the original paper. Many defenses are paired before and after on the same prompts. An ideal analysis would require a paired fourfold table or a McNemar/conditional model, but papers usually do not release paired transition matrices. The current script's independent binomial approximation ignores the correlation, so it is explicitly labeled exploratory.

How to interpret percentages alone. Constitutional Classifiers reports 86%→4.4%. From that one can determine a drop of 81.6 percentage points, a descriptive risk ratio ($4.4/86=0.051$), and a relative reduction of about 94.9%. But without a denominator that can be safely used, no trustworthy standard error can be computed, and the result cannot enter a formal pooling. AdaShield's LLaVA QR goes from 75.75%→15.22%, a descriptive drop of 60.53 percentage points and a ratio of about 0.201. That is still only a comparison within the same study configuration, and it cannot be averaged with the former.

8.5 Random Effects and Paule-Mandel Heterogeneity

Even when studies are judged comparable, the analysis does not assume that a single identical true effect exists. The model is:

$$y_i \sim N(\theta_i, v_i), \quad \theta_i \sim N(\mu, \tau^2),$$

where v_i is the within-study variance and τ^2 is the between-study heterogeneity. The weights are:

$$w_i = \frac{1}{v_i + \tau^2}, \quad \hat{\mu} = \frac{\sum_i w_i y_i}{\sum_i w_i}, \quad SE(\hat{\mu}) = \sqrt{\frac{1}{\sum_i w_i}}.$$

The script uses the Paule-Mandel method to find the τ^2 at which the weighted residual $Q(\tau^2)$ approaches the degrees of freedom $k - 1$. It also reports:

$$I^2 = \max\left(0, \frac{Q - (k - 1)}{Q}\right),$$

along with the mean 95% interval $\hat{\mu} \pm 1.96SE$ and the 95% prediction interval, which suits deployment decisions better:

$$\hat{\mu} \pm 1.96\sqrt{\tau^2 + SE^2}.$$

Finally, the logistic transforms attack proportions back to 0—1, and the exponential transforms risk ratios back to RR. The mean interval answers "where the average true effect may lie", and the prediction interval answers "where the true effect of a new study may lie". When the prediction interval crosses the null line, the average may look as favorable as it likes. Even then, one should not claim that a new deployment is certain to be effective. When $k < 5$, τ^2 and the prediction interval are very unstable, and the main text marks them as low certainty. By default, $k < 3$ is not pooled at all.

8.6 Concrete Implementation and Reproducible Output

The implementation is located at [analysis/meta_analysis.py](#). The script does several things. It rejects `include_meta=false` and verifies $0 \leq \text{events} \leq \text{total}$. It rejects missing values. It rejects multiple arms of the same `study_id` appearing in the same group, and it rejects mixed effect types. It outputs inclusion, rejection, summary tables, a manifest, and an SVG forest plot by `analysis_group`. Raw percentages are not silently filled with zeros, and unknown values are always `NA`.

The formal run results rest on the line-by-line inclusion audit in [data/quantitative_effects.csv](#) and on `analysis/outputs/meta/`. Suppose strict auditing leaves no group with three independent comparable studies. The conclusion will then be "the current evidence does not support a formal pooling", not a lowered threshold that scrapes together a number. Risk reductions, utility losses, and token/latency costs within single studies are still synthesized descriptively.

8.7 Actual Audit and Run Results: Zero Poolable Groups

The unified table deduplicates the original 74 within-paper experimental arms into 34 independent studies, and retains only one pre-declared primary effect for each. Back-deriving event counts from rounded percentages is strictly prohibited. After that step, 29 of those studies can only be interpreted descriptively, and 5 have direct event counts and denominators, but those five belong to five different endpoints.

HOUYI judged 31 of 36 applications vulnerable to black-box application prompt injection. Its point estimate is 86.1%, with a Wilson 95% interval of 71.3%—93.9%. AgentFuzz found 14 taint-style high-risk vulnerabilities in 20 agent applications. Its point estimate is 70.0%, with a Wilson interval of 48.1%—85.5%. AgentDoS found 16 resource-exhaustion/management vulnerabilities in 20 applications. Its point estimate is 80.0%, with a Wilson interval of 58.4%—91.9%. All three label their sampling unit "application", but their vulnerability families, scanners, sampling frames and success definitions differ. They cannot be averaged in

[← Back to contents](#)

to a population susceptibility rate for applications.

On the defense side, CaMeL's selected Gemini-2.5-Pro arm reduced successful attack counts from 300/949 to 0/949, but normal task utility dropped at the same time, from 73.2% to 41.2%. FIDES's GPT-4o raw counts dropped from 9/949 to 1/949, though the authors reinterpret the events again under a policy-violation definition. The two share the same 949 AgentDojo attack opportunities, but their models, baselines, policies and event definitions differ. Their risk ratios cannot be pooled either.

The script run produced these results: 5 passed the numerical contract, 29 were rejected because of `include_meta=false`, and 0 groups were successfully pooled. All five groups were skipped because $k=1$ is below the preset threshold of 3. No forest plot, pooled value, I^2 , or τ^2 was generated. This is not "the analysis was left unfinished". It is a substantive finding of the poolability audit: current public reporting practices are insufficient to answer the average ASR or the average defense risk ratio. The complete item-by-item rationale is in [Inclusion-Exclusion Audit](#) and [Machine Output](#).

9. Correlation Analysis: Computation Steps and the Logic Behind Them

9.1 Why Aggregate by Paper First

A single paper often produces 150 cells across 5 models $\times$ 10 attacks $\times$ 3 defenses. Those cells share data, prompts, author choices and a judge. They are not 150 independent studies. Correlating them directly would give disproportionate weight to papers with large grids and yield extremely small spurious p-values. The script therefore aggregates by `study_id` first. The within-paper mean of a binary encoding is interpreted as the coverage proportion of that paper's encoded experimental arms, and continuous variables take the mean over reported arms. The unit of the main analysis is always the paper.

Candidate variables include year, ASR, adaptive attack, multimodal, agentic, number of independent defense layers, residual ASR, utility change and evidence tier, along with whether independent replication exists. Missing values are deleted pairwise by variable rather than filled with 0. Each pair requires at least 8 studies, and both variables must vary.

9.2 Spearman, Bootstrap, and Permutation Test

Spearman correlation first converts X, Y into ranks separately, then computes the Pearson correlation of the ranks:

$$\rho_s = \text{corr}(R_X, R_Y).$$

When there are no tied ranks it is equivalent to $1 - 6 \sum d_i^2 / [n(n^2 - 1)]$. The actual data contain many ties at 0/1, so the script assigns average ranks to tied values and computes the rank correlation directly. Spearman is chosen because ASR, year and layer count do not satisfy normality/linearity assumptions and contain many extreme values. It measures only monotonic relationships and does not prove causation.

Uncertainty is cross-checked along two routes. The paper-level bootstrap draws n papers with replacement 2,000 times and recomputes ρ each time, and the 2.5% and 97.5% quantiles form the interval. The permutation test holds X fixed and randomly shuffles Y across papers 2,000 times. It uses a two-sided $p = (b + 1) / (B + 1)$, where b is the count of $|\rho_{perm}| \geq |\rho_{obs}|$.

The random seed is fixed at 20260806 to guarantee consistency across repeated runs. The permutation p is not corrected for multiple comparisons and serves only to generate hypotheses for follow-up work. If an interval is very wide or crosses 0, the correct conclusion is that the direction is unstable.

9.3 Mechanism Hypotheses Proposed in Advance

The first hypothesis is that **adaptive attack is positively correlated with residual ASR**, because an attacker who knows the defense can re-optimize. More mature papers, however, are also more likely to conduct adaptive testing proactively, so evidence quality constitutes a confounder. The second hypothesis is that **the number of independent defense layers is negatively correlated with residual ASR**. Permissions, information flow and sandboxes can still block an attack after the model layer fails. High-risk systems, however, may deploy more layers because they face stronger attacks, which gives rise to reverse causation.

The third hypothesis is that **defense strength trades off against the change in normal utility**. Refusal, isolated parsing, repeated inference and human confirmation reduce task completion or increase cost. Also, "layer count" does not represent the quality of each layer. The fourth hypothesis holds that **the relationship between multimodal and attack success rate is unstable**. Differences in image typography, white-box perturbation, direct audio input and GUI actions far exceed a single binary label. Finally, **year is expected to be positively correlated with automated or agentic encoding**. A more likely reading is a shift in research topics and changes in models and benchmarks, not risk caused by the year itself.

9.4 Interpretation Prohibitions

A correlation coefficient cannot answer "how much does adding one defense layer reduce ASR". Nor can it estimate real-world incident rates from a sample of selected papers. Paper-

level means conceal internal heterogeneity, and pairwise deletion changes direction when missingness is non-random. Closed-model versions, attack budgets, judges and publication bias may all jointly affect X and Y. If the effective sample is insufficient, the script does not output that variable pair. If it does output one, that pair serves only as a clue for subsequent stratified experiments, not as a causal conclusion.

9.5 Actual Correlation Results: Mainly a Reflection of a Research-Landscape Shift

Across 34 independent studies, 20 variable pairs reached $n \geq 8$. The clearest observation concerns year and agentic encoding, which are positively correlated. The statistics are Spearman $\rho=0.532$, bootstrap 95% interval 0.277—0.748, and permutation $p=0.0010$. The correct interpretation is that newer studies in this evidence table more often evaluate tool agents. That is consistent with the trajectory of research shifting from chat output to action systems after 2023. It does not mean that the year causes safety risk, nor that the number of agents in real-world deployments grows according to this coefficient.

The result for adaptive attack and residual ASR is $n=9$, $\rho=0.274$, interval -0.143—0.839, permutation $p=0.667$. The direction matches the mechanism hypothesis that "knowing the defense makes bypass easier". The interval, however, is extremely wide, and the current data provide no robust evidence. For ASR and multimodal the result is $n=19$, $\rho=0.295$, interval -0.166—0.648, $p=0.227$. It therefore cannot be claimed that multimodal is inherently easier to attack. Year and ASR give $n=19$, $\rho=-0.279$, interval -0.588—0.125, $p=0.241$, which likewise provides no evidence of a monotonic trend.

ASR and evidence tier give $n=19$, $\rho=-0.438$. The bootstrap interval -0.761—-0.020 appears not to cross zero, but the permutation $p=0.0615$, so the

[← Back to contents](#)

two uncertainty judgments disagree. The tier is merely a discrete source label, and no conclusion is therefore drawn. The $\rho=-0.352$ between multimodal and agentic mainly reflects the current division of papers into two research traditions, "VLM output" and "text tool agents", with a permutation $p=0.082$. It cannot be interpreted as the two techniques being inherently mutually exclusive.

The unified table does not contain enough auditable `defense_layers` encodings, and none of the selected main effects has an independent replication on the same basis. No "layer count-effect" or "replication-effect" correlation was therefore manufactured from subjective impressions. The correlation results are more like a map of research topics than a causal model. The complete 20 pairs of results are given in [correlation analysis report](#).

Study-level exploratory correlations

Intervals and permutation tests describe the sampled literature; they are not causal or predictive.

Research-level exploratory correlation results

For a reproducible implementation see [analysis/correlation_analysis.py](#). The formal outputs are located in `analysis/outputs/correlation/`, including the pairwise n , ρ , bootstrap intervals, permutation p , and the run manifest.

10. Co-evolution of Attack and Defense and Future Trends

10.1 How Trend Analysis Avoids "Predicting by Gut Feeling"

This survey does not present future trends as a product release checklist. It judges direction instead through four observable drivers. The first asks whether research and incident evidence keep appearing. The second asks whether system adoption widens new reachability, permissions and persistence. The third asks whether automation, parallelism and feedback push down the unit cost of attack. The fourth asks whether defense can be enforced by independent components, rather than continuing to rely on model self-discipline. A positive "year—agentic" correlation at the research level supports only a shift in research topics. It cannot prove that real-world risk grows with the year. Each item below therefore gives the mechanism, the observable signals and the uncertainty together.

10.2 The Main Axis of the Next Two Years Will Shift from Generated Content to Long-Horizon Action Chains

One near-term trend carries high confidence. Security evaluation is shifting away from "whether a single-turn answer violates policy" and toward "whether an agent can, within hours, find an entry point, maintain state, call tools, and escalate permissions." Prompt attacks are already automated by PAIR, GPTFuzzer and similar work. AgentDojo, InjecAgent and similar benchmarks push the endpoint forward to tool actions. The 2026 OpenAI—HF incident in turn shows the same direction. A cybersecurity agent whose refusals were lowered for evaluation purposes could produce roughly 17,600 consecutive actions and iterate across complex agents, third-party harnesses, cloud identities and internal networks. Growth in attack

capability need not appear as a single higher ASR. What matters more is that each round of effective feedback costs less, that failure triggers automatic rerouting, and that context holds over long periods.

Observable signals will include more tool steps per task and more parallel agents. Automatic credential discovery and permission graph search will enter general-purpose harnesses. Security evaluation will begin to report time-to-compromise, steps before the first dangerous action, total cost and human intervention points. Defensive focus will turn to action-level budgets, staged authorization, revocable identities and anomaly detection over long trajectories, and away from text filtering at the end of the pipeline. One uncertainty remains. Closed-source models and infrastructure change rapidly. The attack chain of a single incident cannot be extrapolated directly into a general success rate.

10.3 Multimodal Risk Will Move from "Text Hidden in Images" to Persistent Environment State

FigStep, HADES, SpeechGuard and GUI injection have already shown the pattern. Image layout, visual representation, audio waveforms and interface elements each enter the model through a different parser. The risk of the next stage is not simply that these attacks merge into "multimodal ASR." Vision, audio, video, OCR, ASR, DOM and action history instead form a persistent state. An instruction may be incomplete in a single frame, yet it may alter behavior once frames or modalities are combined. Real VLAs and robots add erroneous clicks, movement and physical contact to this picture, with irreversible consequences.

The observable signals are shifts in benchmarks from static question answering toward trajectories that carry timestamps, region-level provenance, screenshots before and after actions, and physical constraints. Defenses will in turn require multi-parser consistency, preservation of the original modality, provenance that propagates with summaries, and out-of-model safety constraints such as speed, space, collision and emergency stop. Current public evidence still leans toward static images. The local VLM reproduction reported in this survey produced no valid answers, owing to 9/9 timeouts. Quantitative trends for audio-video and embodied systems can therefore be labeled only medium confidence, and the numbers from FigStep cannot be used as a substitute.

10.4 Memory Will Be Treated as a Security Database, Not as a Longer Context

AgentPoison, MINJA, A-MemGuard and the memory attacks that followed turn a single input into a three-stage chain of write, recall and action. Personal assistants and enterprise agents will store more preferences, summaries, tool results and user profiles. Memory systems will then face provenance forgery, cross-tenant confusion, dormant triggers, compositional poisoning, incomplete deletion and backup resurrection at the same time. The model "believing this memory to be trustworthy" will not become a reliable control. Tenant, subject, purpose, integrity, confidentiality, TTL, version, derivation chain and tombstone will become minimum requirements, just like a database schema.

Papers and products begin to report write success rate, future top-k recall rate, conditional action rate, survival time, cross-tenant leakage and verifiable deletion separately, instead of a single final ASR. That is one observable signal. The sign of mature defense is likewise not one more memory classifier. It is that identity filtering happens before vector retrieval, that trust escalation requires external evidence, that derived summaries inherit provenance, and that recovery flows replay deletion markers. System adoption pushes this direction strongly. Long-term real-world reproductions, however, remain few, and the effectiveness of specific defenses carries low to medium certainty.

10.5 The Harness Will Become the Trusted Computing Base and the Primary Audit Object

The stronger the model, the less the harness can get away with mere string concatenation and function forwarding. Task decomposition, tool registration, schemas, parameter normalization, authorization, retries, memory writes, secret issuance, networking and logging all converge here. Any design in which "the model judges for itself whether it is safe" forms an authorization layer mismatch. Future high-risk systems will treat model output as a candidate plan with provenance. A small, auditable policy kernel will then decide whether to execute it, weighing the user, the task, the resource, the data labels and the consequences.

Technical paths will move toward capability types, information-flow labels, policy as code, two-phase commit, parameter-hash-bound approval and formal invariants. The properties that can truly be verified are not "the model is never subject to injection." They are "a low-integrity web page cannot directly determine the parameters of a high-impact tool," "user B's data cannot flow into user A's answer" and "an unapproved recipient cannot receive any outbound content." CaMeL, FIDES, Task Shield and MCP security practices provide early forms, but adapters and label loss remain part of the trusted computing base. A formal model becomes engineering-meaningful only once it covers real tools and side effects.

10.6 Sandboxes Will Shift Toward Disposable Execution Units and External Capability Proxies

No single winner will replace containers, WASM, gVisor and microVMs across every scenario. The trend is to choose the minimal semantics each workload needs. Pure extraction avoids a general-purpose executor wherever possible. Small plugins use WASM with explicitly imported capabilities, and native untrusted code enters a per-task short-lived VM. Network, secrets and cloud identity are in turn issued temporarily by a broker outside the sandbox, once an action passes policy. The reason is that execution isolation, network isolation, secret isolation and resource isolation are not equivalent to one another. Any single covert egress path breaks the boundary as a whole.

Security statements will be the observable signals. They will move from "runs in a sandbox" to versioned allow/deny matrices, kernel or VMM boundaries, egress policies, IMDS blocking, credential lifetime, proof of destruction and recovery time. Threat modeling for package proxies, third-party code harnesses, shared infrastructure and internal networks will follow,

especially after HF incidents. Zero-days remain irreducible. Short-lived execution, no long-lived secrets, deny-by-default egress and rapid rebuilds are therefore more testable than a claim of “absolutely no escape.”

10.7 Supply Chain Objects Will Expand from Weights to the Full Set of Agent Artifacts

A future model bill of materials will cover, all at once, weights, adapters, tokenizers, processors, chat templates, system prompts, tool descriptions, MCP servers, policies, containers, GPU extensions and evaluation harnesses. A malicious pickle is only one entry point among them. Safe tensors may also carry backdoored behavior. Trusted weights may be paired with malicious tool descriptions, or with policies that are too broad. The 2025 PyTorch weights_only vulnerability, the unauthorized Cline npm release and the 2026 HF incident together show the pattern. AI supply chain risk is often conventional signing, CI/CD, credentials and release permissions superimposed on model control flow.

Observable signals here include organizations pinning versions and digests for the complete runtime graph and generating provenance for training, conversion, quantization, evaluation and packaging. Production no longer follows a floating latest. Artifacts are re-signed after passing behavioral gates and enter an internal read-only registry. Models, tools, policies and credentials can be revoked jointly. The misunderstanding to avoid above all else is treating safetensors, a signature or an SBOM as a standalone certificate of behavioral safety.

10.8 Evaluation Will Shift from ASR Leaderboards to Conditional Risk Chains and the Security-Utility-Cost Frontier

A single ASR cannot say where the harmful impact is cut off. A more explanatory end-to-end event chain can be written as:

$$P(H) = P(R) P(C | R) P(I | C, R) P(A | I, C, R) P(H | A, I, C, R),$$

where ***R*** denotes that the attack input is reachable, ***C*** that the task or state is controlled, ***I*** that a harmful intent arises, ***A*** that the executor authorizes and executes, and ***H*** that actual harm occurs. This expression is chain-rule accounting expanded over conditional probabilities, and it does not require the stages to be independent. Its value lies in identifying which term a defense actually changes. If only zero final harm is observed, the cause may be that the input never arrived, the model never triggered, a capability gate denied it, or the experiment had no valid response at all. These four causes must not be conflated with “safe.”

Future high-quality benchmarks should release stage counts, benign tasks, false refusals, tokens/latency/human effort/cost, attack budgets, and model and harness versions at the same time. They should also provide paired transitions of the same prompt before and after a defense. The meta-a

udit in this survey yields zero poolable groups. That shows precisely that common reporting today is not yet sufficient to estimate the average true effect. Only as independent replications across multiple organizations, across models and at identical endpoints gradually appear will random effects, prediction intervals and causal stratification become more meaningful than a descriptive map.

10.9 Which Popular Narratives Should Not Be Taken as Trend Conclusions

“Smarter models are naturally safer” and “stronger models are necessarily more dangerous” both lack monotonic evidence. Capability, alignment, tool permissions and deployment boundaries all change at the same time. The so-called “end of universal jailbreaks” usually holds only under a fixed policy, a fixed model version and a fixed attack budget. Adaptive retesting may rewrite the result. So-called “fully automated AI defending against AI” is merely a loop of correlated failure when the same kind of model generates, executes, scores and approves at once. A more credible direction is for models to take on discovery, explanation and candidate planning. Independent identity, policy, information flow, execution isolation and human accountability keep the final authorization.

11. Engineering Deployment, Minimum Evidence Checklist, and Conclusions

11.1 Write Actions and Assets First, Then Prompts

Before deployment, first enumerate the real changes the system can cause. Work through the data it reads, the state it writes and the parties it sends to. Then check whether it can pay, whether it can run code, whether it can modify release artifacts and whether it can acquire new identities. Bind every class of action to a calling principal, tenant, object, parameters, network, secrets, resource budget, reversibility and approver. The threat model then enumerates entry points, failure boundaries and consequences along a unified taxonomy. Suppose a team knows only how to “prevent prompt injection.” If it cannot say what the model could do after a successful injection, security design has not yet begun.

11.2 Data, RAG, and Memory Must Be Identity-Isolated Before Entering the Model

ACL, tenant and purpose filtering must be enforced before retrieval. Do not put unauthorized data into the prompt and then rely on the model to keep it secret. External web pages, documents, OCR, tool outputs and automatic summaries are low-integrity by default. They carry their provenance into downstream variables, summaries and cross-agent messages. Memory writes require an independent policy, and the model cannot approve its own trust escalation. Deletion requires synchronized tombstones, index withdrawal, derivative tracking

and backup-restore replay. Benign utility testing must confirm that security filtering has not stripped out facts the task needs.

11.3 The Release Standard for a Harness Is That Actions Cannot Self-Authorize

Model output first enters a read-only plan object. It then passes review of registration, task, data flow, parameters and consequences. High-impact actions use dry-run and two-phase commit. Approval is bound to canonicalized parameters, tool version and expiry time, and any change invalidates the approval. An external policy computes permissions as a minimal allow set. The model has no ability to expand scope, extend tokens, change tenants or disable logging. Safety classifiers may participate in scoring and escalation. They cannot, however, form the sole authorization chain together with the same model that generated the action.

11.4 Verify Execution, Network, Secrets, and Budget Separately

Sandbox acceptance should rely on real probes, not on the names in a configuration. At a minimum, the probes must verify in-scope reads and writes, out-of-scope reads and writes, process creation, DNS/redirection, loopback/private network/link-local/IMDS, device and host mounts, resource exhaustion and residue after destruction. Secrets do not enter the model context. Once an action is approved, a broker issues short-lived, audience-bound, minimal-scope credentials. Code execution and network evaluation should preferably run in disposable, strongly isolated units with no long-lived secrets and default-deny egress. Those units should be destroyed immediately when the task ends.

11.5 Release Gates Must Have Security, Utility, and Cost Thresholds Simultaneously

Report results separately for each action family: dangerous intent, dangerous execution, actual side effects or strict simulation, benign task success, false refusal, latency, token, tool steps and cost. For small samples, use intervals rather than reporting only zeros. Before-and-after comparisons on the same case must retain paired transitions. Never treat multiple cells from the same paper or the same seed as independent samples. For high-impact actions, acceptance turns on the one-sided upper bound of the dangerous execution rate and on the blast radius. The average refusal rate is not the test. If a test yields a request error or an empty response, that cell is recorded as undecidable or as an availability failure. It must not automatically count as safe.

11.6 Monitoring and Incident Response Must Be Able to Reconstruct the Entire Causal Chain

A unified trace must at minimum link the original user goal, context provenance, planning, model and prompt versions, tool schema, canonicalized parameters and policy decisions. It must also link human approval, credential issuance, network, files, memory writes and

deletions, sandbox events and resource budget. After a detection fires, first freeze new actions, revoke identities, block egress and preserve forensic evidence. Then rotate credentials, rebuild the environment and purge index and memory derivatives. Finally, convert known entry points and detection signals into regression gates. Alerts with no on-call escalation, or logs with no action-ID correlation, do not add up to response capability.

11.7 Evidence Limitations of This Survey

Search candidates have been deduplicated and the raw API responses saved. No completed PRISMA log yet excludes all 1,854 candidates by title, abstract and full text. This survey therefore does not claim to be exhaustive over all papers. The attack, defense and incident base tables use different units and cannot be summed into a total paper count. If backfilling for the formal version continues, evidence-level statistics may still change. Most papers lack direct incident counts, paired transitions, independent replication and production side effects. The formal meta-analysis therefore yields zero pooled groups. The correlation is exploratory, over 34 selected studies. It does not represent the distribution of real-world incidents, nor a causal effect.

We used the local text-based harness and the macOS sandbox experiments to validate mechanisms. The harness is constrained by a single seed across six scenarios; the macOS sandbox is constrained by the deprecated sandbox-exec. The former does not execute real side effects, and the latter does not test escape. The VLM experiment obtained no valid responses, so it can only report a runtime timeout. Technical retrospectives from both sides of the 2026 OpenAI-HF incident have already provided substantial facts. OpenAI's more complete technical report had still not been published as of the materials cutoff, and some attribution and control details may continue to be updated.

11.8 Conclusions

The core tension in LLM security is not “how to find a prompt that can never be jailbroken.” It is that a natural-language planner works on incomplete, corruptible and probabilistic context, while real systems tend to give it persistent state and high-privilege capabilities. Jailbreaks, RAG poisoning, indirect injection, VLM attacks, memory poisoning, malicious tools and supply chain vulnerabilities appear scattered. Yet all of them come down to three questions. Does untrusted data gain control influence? Can a model proposal cross authorization on its own? Is the impact of a failure isolated and detected?

Model alignment remains necessary, because reducing dangerous intent eases the pressure on downstream lines of defense. But the most robust security gains come from independent boundaries outside the model. Provenance and tenancy are enforced before retrieval. Model output is only a proposal. Each action is approved by capability and information-flow policy. Network and secrets are minimized. Arbitrary code enters short-lived isolated units. Memory is traceable and deletable, and the entire trace is forensically auditable. The 2026 HF incident reminds us that naming an environment a “sandbox” does not automatically shut down package proxies, third-party harnesses, long-lived credentials and lateral networking. Security

conclusions hold only when the allow/deny matrix, real probes, utility cost and failure records are all reviewable.

The most important quantitative conclusion of this survey is therefore restrained. Existing evidence is insufficient to compute a trustworthy “overall LLM compromise rate.” No like-for-like group among the 34 independent studies reaches three poolable studies. The exploratory correlation mainly shows research topics migrating toward agentic systems. More useful than a striking average is clarity. Which link of the attack chain is cut, and are normal tasks preserved? How does residual risk reach real assets, and can the conclusion be re-verified after the next model, tool or policy update?
